PLACING CALIBRATION LINE ON A KIMBLE VOLUMETRIC FIPETTE, a coordination of skilled hand and precision machine.

At no time in the production of Kimble Exax Blue Line Glassware is the skill of human hand and brain eliminated. In certain glass-making operations the "human equation" is vitally important, and is employed by Kimble to do that which the hand can perform better than any mechanism.

At no time does Kimble sacrifice thoroughness and accuracy for speed. Every operation is studied and planned to fabricate only the best that brains and machinery can produce. It is this careful coordination of human ingenuity and mechanical perfection that places Kimble Scientific Glassware where it is today . . . the Standard for "Assured Accuracy" wherever laboratory research, analysis, test and control work goes on.

Stocked by leading Laboratory Supply Houses throughout the United States and Canada.

IF THE *Telephone* WERE NOT THERE!

MANY times each day you reach for the telephone on your desk at the office or in its familiar spot at home. It is an old and trusted friend. You scarcely give a thought to what it means to a busy day.

Yet suppose the telephone were not there! Suppose—for a week—or a month—you could not call anybody by telephone and nobody could call you. The whole machinery of business and the home would be thrown out

of gear. Orders would be lost—efficiency and profits reduced. You would be out of touch with your world.

America needs quick, reliable telephone service to get things done in the brisk, crisp American manner. And it enjoys the best service in the world.

Greater progress has been made in this country because of the Bell System's one policy, one system and universal service.

America leads in telephone service. In relation to population, there are six times as many telephones in this country as in Europe and the telephone is used nine times as much.

BELL TELEPHONE SYSTEM

Concentrated Anti-pneumococcic Serum SQUIBB

SUCCESSFUL SERUM TREATMENT of pneumonia (Type I or II) depends upon early administration. Adequate dosage is equally important.

Anti-Pneumococcic Serum Types I and II Squibb is refined and concentrated essentially by methods developed by Dr. Lloyd K. Felton of Harvard University Medical School. It supplies in a volume of about 10 cc. the same number of antibody units as are contained in 100 cc. of unconcentrated serum. Chill-producing substances and inert proteins and lipoids have been removed to a marked degree.

Anti-Pneumococcic Serum Concentrated is supplied in syringes containing, in about 10 cc., 10,000 units of Type I and 10,000 units of Type II anti-pneumococcic antibodies. Also supplied in 10-cc. syringes containing 20,000 units of Type I and Type II anti-pneumococcic antibodies.

If your druggist does not have Anti-Pneumococcic Serum Squibb in stock, request him to wire the nearest Squibb Branch or Depot. Emergency orders always receive prompt attention.

IMPORTANT FACTS FOR THE CHEMIST ON

Pyrex LAMP-BLOWN APPARATUS

FUNNELS

SPECIAL APPARATUS

EXTRACTION APPARATUS

STOPCOCKS

THE COST of all lamp-blown chemical apparatus is relatively high. It involves more handwork than on the more simple-shaped beakers and flasks. Your investment in costly apparatus is best protected by the "PYREX" trade-mark.

In the Corning Lamp Shops skilled workers are aided by the latest developments in glass technology. "PYREX" brand glass allows the fullest application of their skill; they have the benefit of equipment specially designed for working "PYREX" glass; and construct apparatus mostly from mould blown blanks of uniform wall thickness instead of less uniform and less rugged blanks fabricated from tubing.

Their finished product goes through time-and-temperature controlled lehrs, insuring correct annealing.

They have the aid of technologists who understand both the chemist's requirements and the art of glass blowing.

The unusual chemical and physical properties of "PYREX" brand glass, combined with skilled workmanship guided by scientific supervision, insure the production of laboratory apparatus of outstanding quality.

Be sure that the "PYREX" trade-mark below is reproduced *exactly* on every piece of laboratory apparatus you buy.

NOW

for just One Dollar a
year

you can keep in touch
with latest developments
in sanitary practice

You can now have MUNICIPAL SANITATION on your desk each month for \$1 a year.

Men interested in maintaining the well being of a city will find material of real practical benefit in every issue of this interesting monthly. No less an authority on matters of Public Health than Hugh S. Cumming, Surgeon General, U. S. Public Health Service, has this to say of MUNICIPAL SANITATION.

"All those interested in the future of sanitation development will do well to coöperate in the wider use of this publication."

Surely every member of the A.P.H.A. should be a reader of MUNICIPAL SANITATION.

Every one means to improve his condition by more extensive reading of the right sort. Nothing a Sanitary Engineer, or any one interested in Sanitation, could read would bring more helpful information than 12 copies of Municipal Sanitation.

Use the coupon NOW

This reduction, from the two dollar rate effective since the publication's founding in 1930, is made as our contribution to a resumption of normal spending for sanitation purposes among the towns and cities of the country, the "back to normalcy" movement that is so tremendously needed.

Take a look in this Ultra-Microscope, Doctor!

You are now helping to conduct one of the several tests which every batch of Knox Sparkling Gelatine undergoes before it is released for invalid use. Gelatine is a protective, reversible colloid of the emulsoid type. Under this ultra-microscope you will see the Brownian movement of the gelatine microns. The test is relatively unimportant except as a test for clarity, but it is one of those little things we are fussy about.

Other, and more important to you are these factors for which every batch is tested: a pH of about 6; bacteriological safety; absence of carbohydrates and a total metal tolerance less than half that specified by the U.S.P. *All gelatine products are not U.S.P. so be sure your patient gets a U.S.P. gelatine or better.*

Quite a remarkable product—Knox Gelatine. Made as carefully as an ampule solution. For the convalescent, tubercular, high-protein, post-operative, diabetic and infant diet where higher protein content is desirable.

FIFTY YEARS OF PROGRESS

IN 1885, fifty years ago, the American Telephone and Telegraph Company was formed.

There were few telephones then and service was slow, uncertain and limited to separate communities. In that year the largest number of telephones in any one city was 8400, in New York.

New York now has 1,500,000, Chicago 800,000, Philadelphia 350,000.

From your own Bell telephone you may talk with any one of 17,000,000 other telephones in this country and most of those in foreign lands. Today, 93% of all the world's telephones are within reach of the Bell telephone in your home or office.

This year marks also the Twentieth Anniversary of the opening of the first transcontinental line, from New York to San Francisco, and the Eighth Anniversary of the opening of transatlantic service.

The work of improving Bell telephone communication is never ended . . . it goes on and on toward a constantly higher standard. Further improvements as important as those of the past half-century will come through Bell System research, manufacturing and unified operation.

To make your telephone service dependable, 91 per cent of the Bell System's 80,000,000 miles of wire is now in storm-resisting, lead-covered cable. Sixty-five per cent of it is buried beneath the ground.

BELL TELEPHONE SYSTEM

Reprint prices furnished upon request

Of interest to your patient, Doctor. We just want to point out that one box of Knox Gelatine makes four pints of jelly . . . a ready source of protein of exceptional purity and fineness . . . at a truly reasonable price.

The total metal tolerance of Knox Gelatine is less than half that specified by the U.S.P. Knox Sparkling Gelatine contains no carbohydrates, is bacteriologically safe and has a pH of about 6. When gelatine is required in the diet, why not let your patient have U.S.P. or better?

Not all Jelly products are U.S.P., you know. We suggest Knox.

A remarkable product—Knox Gelatine. Made as carefully as an ampule solution. For the convalescent, tubercular, high protein, post-operative, diabetic, and infant diet where higher protein content is desirable. Of course, a gelatine manufactured so carefully is completely odorless.

KNOX SPARKLING GELATINE

Each Kimble Blue Line Exax Volumetric Flask is carefully re-tested by scientific methods—by thoroughly trained technicians.

VERY scientific requirement for accuracy, quality and fine workmanship is embodied in the Kimble Blue Line Exax Volumetric Flask.

These flasks are made from selected blanks to eliminate objectionable blisters, stones and streaks. Walls are strong and shock-resisting. Each flask is retempered (strain-free) in a special annealing oven. Lines and numbers are acid-etched and filled with a durable fused-in blue glass. Glass stoppers are ground to a perfect, leak-proof fit. Stoppers and flasks have corresponding identification numbers.

The following limits of error assure a high degree of accuracy:

Size	Calibrated to Contain	Calibrated to Deliver
10 ml.	± 0.06 ml.	± 0.10 ml.
25 ml.	0.06 ml.	0.10 ml.
50 ml.	0.10 ml.	0.20 ml.
100 ml.	0.16 ml.	0.30 ml.
200 ml.	0.20 ml.	0.40 ml.
250 ml.	0.24 ml.	0.50 ml.
500 ml.	0.30 ml.	0.60 ml.
1000 ml.	0.60 ml.	1.00 ml.
2000 ml.	1.00 ml.	2.00 ml.

**MORE
THAN A**

Million People

**OWN OR OPERATE
THE BELL SYSTEM**

THE Bell System furnishes a nation-wide telephone service to a great and populous country—a service used for 59,000,000 talks a day. Telephone conversations per capita in this country are more than nine times as many as in Europe.

It takes 275,000 trained people to build and operate the switchboards, wires, cables, and other apparatus that make this service possible. It has taken the savings of 850,000 people to pay for the plant and equipment of the Bell System. Six hundred and seventy-five thousand own stock in the American Telephone and Telegraph Company, and in many instances other Bell

securities. Another 175,000 own Bell System bonds or stock in the operating telephone companies. No other business organization is so widely owned by so many people.

Since its beginning more than 50 years ago, the Bell System has rendered a constantly improving service more and more indispensable. Usefulness to the public is the motive that keeps the telephone business going. In the true sense of the word, this is a democracy in business.

More than half the stockholders of the American Telephone and Telegraph Company, the parent company in the Bell System, are women. Nobody owns as much as one per cent of the stock.

Essentials of Tissue Culture Technique

by Gladys Cameron

COMPLETE information on equipping a laboratory and acquiring the technique of growing successful cultures. The author has had vast experience in this field, having worked under the famous Dr. Carrel in the tissue culture laboratory of the Rockefeller

Institute over a number of years, and at present as associate of Dr. Chambers at New York University. This is an authoritative, thoroughly practical guide to the subject. Fully illustrated, approx. 160 pages, *probable price*, \$2.50.

An Introduction to Sex Education

by Winifred V. Richmond, Ph.D.

A SIMPLE, authoritative and courageous study of sex by one of the most prominent and experienced woman psychologists in the country. The author, through her personal experience in teaching nurses and at

St. Elizabeth's Hospital, Washington, D. C., has created an astute, brilliant book of special value to nurses. 312 pages, illus. and indexed, *College Edition*, \$2.00.

THE IMPORTANCE OF *Heat Resistance* IN LABORATORY GLASSWARE

"IS it heat resistant?" may well be the first thought of the chemist in selecting his laboratory glassware. The use of Laboratory Ware without good heat-resisting properties is a serious handicap in everyday laboratory operations—the cause of broken glassware, lost time, lost effort, and wasted materials.

Furthermore, laboratory vessels made from glasses which are not heat-resisting must be blown with thin walls to provide some measure of resistance to heat and sudden temperature changes. This sacrifices mechanical strength and weakens the ware against the mechanical shocks of everyday service.

"PYREX" brand Laboratory Ware gives the chemist the utmost in strength and dependability—more resistance to heat and to sudden temperature changes—(because of its low coefficient of thermal expansion— $0.0000032/^{\circ}\text{C}.$)—more resistance to chemical attack and mechanical shock; correct annealing, and accuracy.

Because the good qualities of "PYREX" Laboratory Ware are universal—and inexpensive—it is generally preferred for all types of laboratory work—research, testing, and educational.

The ware is sold through leading laboratory supply dealers in the United States and Canada.

"PYREX" VOLUMETRIC FLASKS

Accuracy, plus heat resistance, chemical stability, and mechanical strength.

"PYREX" is the registered trade-mark of

Milks Fortified

under license of VITEX Laboratories, Inc.,
contain 400 U.S.P. Vitamin D Units per quart

derived from Cod Liver Oil

May we supply you with technical information and reprints of clinical studies regarding Vitamin D milks containing the Vitamin D concentrate, Vitex.

We confine our statements to the consumer to the following:

- (1) Each quart has an added Vitamin D content of 400 U. S. P. Units.
- (2) The Vitamin D used is extracted from Cod Liver Oil by a process developed in the laboratories of and controlled by Columbia University.
- (3) These Vitamin D milks containing Vitex are the best of pasteurized milk—with an enhanced nutritional value.
- (4) These milks containing Vitex are accepted by the Committee on Foods of A. M. A.
- (5) They are regularly assayed in cooperating biological laboratories.

Vitex Laboratories, Inc.

A subsidiary of National Oil Products Co.

VITEX LABORATORIES, Inc., Harrison, N. J.

Please send me technical information and reprints of clinical studies made with Vitamin D milks fortified with Vitex.

LATENT AVITAMINOSIS:

THE "TWILIGHT ZONE" OF NUTRITION

Each passing year discloses that the science of medicine has made further application of the results of biochemical research. The time will come when the physician will rarely see examples of extreme human avitaminosis. The high vitamin requirements of infancy and childhood are clearly recognized; they are fulfilled by proper supplements to the diet. The cooperation of intelligent parents will certainly aid in decreasing the incidence of deficiency diseases of childhood.

The matter of the adult vitamin requirement has also received attention; the average individual understands his dietary needs, in a general way. As a result, if the pellagrin be excepted, the practitioner today seldom encounters *extreme* vitamin deprivation in his patients. The fight against vitamin deficiencies is changing in aspect; the problem now is to combat *suboptimal* rather than *subminimal* vitamin intake.

In 1920, Hess described the condition of subacute or "latent scurvy". Evidence since accumulated indicates that similar conditions may exist in respect to the other essential vitamins. This latent avitaminosis has been aptly termed the "twilight zone" of good nutrition (1).

Latent avitaminosis is a state of ill-health difficult to define; it may be characterized

by a vague, indefinite sense of ill-being; it is a condition, however, which responds to proper diet under medical supervision; and among the most valuable foods available for diets in cases of latent avitaminosis are canned foods. The literature is replete with articles relating to the vitamin values of canned foods; several of these are particularly pertinent to the present discussion (2).

Two species of laboratory animals, the albino rat and the guinea pig, were carried through ten and eight generations, respectively, on a diet which consisted entirely of combinations of canned foods. No additional vitamin supplements, such as are commonly employed in the breeding or rearing of such animals, were necessary. The varied canned food diet supplied all factors, vitamin or otherwise, for the successful fulfillment of the life cycle, namely growth, maintenance, reproduction and lactation.

The significance of these findings is obvious. The physician may prescribe a diet containing a wide variety of canned foods with the confidence that the combination will supply essential vitamins in amounts consistent with the amounts of the vitamins present in the raw materials from which the canned foods were prepared. Whether additional supplementation with specific vitamin-rich foods or concentrates is indicated, is properly a matter for medical determination.

THE IMPORTANCE OF

*Heat Resistance*IN LABORATORY
GLASSWARE

"IS it heat resistant?" may well be the first thought of the chemist in selecting his laboratory glassware. The use of Laboratory Ware without good heat-resisting properties is a serious handicap in everyday laboratory operations—the cause of broken glassware, lost time, lost effort, and wasted materials.

Furthermore, laboratory vessels made from glasses which are not heat-resisting must be blown with thin walls to provide some measure of resistance to heat and sudden temperature changes. This sacrifices mechanical strength and weakens the ware against the mechanical shocks of everyday service.

"PYREX" brand Laboratory Ware gives the chemist the utmost in strength and dependability—more resistance to heat and to sudden temperature changes—(because of its low coefficient of thermal expansion— $0.0000032/^{\circ}\text{C}.$)—more resistance to chemical attack and mechanical shock; correct annealing, and accuracy.

Because the good qualities of "PYREX" Laboratory Ware are universal—and inexpensive—it is generally preferred for all types of laboratory work—research, testing, and educational.

The ware is sold through leading laboratory supply dealers in the United States and Canada.

**"PYREX"
VOLUMETRIC
FLASKS**

Accuracy, plus heat resistance, chemical stability, and mechanical strength.

AWAY FROM THE HEAT AND HURRY OF THE CITY

Well-known to the city dweller is the longing for green fields and growing things. For the peace and comfort of a house by the side of a quiet road. Where the air is fresh and clean and tall trees shade the day. The telephone has helped to make that dream come true for countless men and women.

Long miles may separate your office from your home, yet you are never far away. It takes but a moment for you to call your wife or child. And they have but to lift the receiver to be in touch with you, with friendly neighbors, with guardians of their welfare.

Telephone service like this is the result of years of effort by the Bell System. Bell Telephone Laboratories contribute their research and engineering. Western Electric its manufacturing, purchasing and distributing. The 24 regional telephone companies, with the assistance of the American Telephone and Telegraph Company, see that the latest improvements in the art are available to all.

Placing calibration lines on a Kimble Blue Line Exax Pipette—an operation requiring skill and accuracy.

Kimble Blue Line Exax Pipettes...in addition to their "assured accuracy" and dependability...have many valuable features of construction:

They are made of automatic-machine-made tubing...straight, thick-walled and of very uniform bore. They are retempered (strain-free) for maximum strength. All

lines and numbers are deeply acid etched and filled with a durable blue glass, fused-in. Expertly calibrated at 20° C. Main division lines completely encircle tube. Tip openings deliver contents accurately and at proper speed.

Every Blue Line Exax Pipette is retested to these tolerances:

Volumetric and Ostwald Pipettes

Size	Tolerance	Size	Tolerance
1 ml.	± 0.012 ml.	15 ml.	± 0.06 ml.
2 ml.	0.012 ml.	20 ml.	0.06 ml.
3 ml.	0.02 ml.	25 ml.	0.06 ml.
4 ml.	0.02 ml.	50 ml.	0.10 ml.
5 ml.	0.02 ml.	100 ml.	0.16 ml.
10 ml.	0.04 ml.	200 ml.	0.20 ml.

Measuring and Serological Pipettes

1/10 ml.	±0.005 ml.
2/10 ml.	0.008 ml.
1 ml.	0.02 ml.
2 ml.	0.02 ml.
5 ml.	0.04 ml.
10 ml.	0.06 ml.
25 ml.	0.10 ml.

Standardize on Blue Line Exax Pipettes...for assurance. A full line of Kimble Exax glassware is stocked by leading Laboratory Supply Houses throughout the United States and Canada.

Kellogg's ALL-BRAN may be served in many delicious ways

VARIETY has strong psychological value in any diet. Attractive, new dishes maintain interest and stimulate appetite. Where the diet permits the use of "bulk," Kellogg's ALL-BRAN is doubly convenient.

This natural laxative food may be served as a cereal with milk or cream, or cooked into appetizing muffins, breads, waffles, etc. It blends better with other ingredients in the recipe. ALL-BRAN may also be taken in orange juice, sprinkled in soups, over salads or other cereals.

ALL-BRAN supplies gentle "bulk" to aid regular habits. Within the body, this "bulk" absorbs moisture, and forms a soft mass. Gently, this sweeps out the intestinal wastes. ALL-BRAN also furnishes vitamin B and iron.

Except with those few individuals who suffer from diseased or highly sensitive intestines, where "bulk" in any form is inadvisable, Kellogg's ALL-BRAN may be safely used. Sold by all grocers in the red-and-green package. Made by Kellogg in Battle Creek.

A Second test OF VITAMIN D MILK

AS medical research gains further knowledge about various Vitamin D Milks, it is reflected in new requirements made by the Committee on Foods of the A. M. A. for accepted Vitamin D milks to keep pace with the facts.;

Vitamin D milks fortified with Vitex derived from Cod Liver Oil contain 400 U.S.P. Vitamin D units per quart. This is equivalent in Vitamin D content to $1\frac{1}{4}$ teaspoonfuls of the new minimum standard U.S.P. Cod Liver Oil.

The Committee on Foods of the A. M. A. has issued a recent requirement as to what the producers of the various Vitamin D milks may say about the effect of each accepted milk in promoting growth. According to this requirement the following may be claimed for Vitamin D milk fortified with

Vitex: "It is antirachitic for the normal infant when taken in the usual quantity of one and one-half pints daily and will promote good growth."

The potency of milk fortified with Vitex is controlled in two ways. Licensee contracts require monthly control-reports stating the quantity of Vitamin D concentrate used and the quantity of Vitamin D milk produced. These reports are available at all times to Vitex Laboratories, Inc., and all interested Federal, State and City food control officials and to the Committee on Foods of the A. M. A.

The second control method is through regular bio-assay reports made through independent laboratories. These assay reports also are made available to interested food control officials and to the Committee on Foods.

Vitex Laboratories, Inc.

A Subsidiary of the National Oil Products Co.

Kimble stopcocks are carefully ground by hand and are vacuum tested. The grinding process is one of the most important steps in making an Exox Burette.

WHEN you specify "Exox" Burettes you secure, in addition to "assured accuracy" and dependability, these valuable Kimble features of construction:

Kimble Blue Line Exox Burettes are made of automatic-machine-made tubing, straight, thick-walled and of very uniform bore. NEW AND LARGER STOPCOCKS are used—accurately ground and tested against a vacuum of 15" of mercury. Stopcock barrels are sealed directly to burette tubes for increased strength. Rubber washer on end of stopcock plug prevents slipping, loss and breakage. Delivery stems cannot trap air, and tip openings deliver liquid accurately and evenly.

Blue Line Exox Burettes are retempered (strain-free) in a special annealing oven. They are carefully calibrated at 5 points at 20°C, and lined and numbered by automatic machines. All lines and numbers are deeply acid-etched and filled with a brilliant durable BLUE GLASS, fused in. All main division lines completely encircle the tube.

Exox Burettes are individually retested to these tolerances:

10 ml.	±0.04 ml.
25 ml.	0.06 ml.
50 ml.	0.10 ml.
100 ml.	0.20 ml.

For the sake of assured accuracy and service, SPECIFY EXOX. Stocked by Laboratory Supply Houses throughout the U. S. and Canada.

Years of Progress

HAVE BROUGHT MANY IMPROVEMENTS IN
TELEPHONE SERVICE

IN THE early days of the telephone, practically all wires were carried overhead on poles or on house-tops. Some of the tallest poles carried thirty cross-arms and three hundred wires.

If the old system were in use today the streets of our larger cities would scarcely have room enough for their canopy of wires. Traffic would be impeded, telephone service subjected to the whims of nature.

Better ways had to be found and the Bell System found those ways. As many as 1800 pairs of wires are now carried in a cable no larger than a baseball bat. Ninety-four per cent of the Bell System's 80,000,000 miles of wire is in cable; sixty-five per cent of it is beneath the ground.

This has meant a series of conquests of space, and insured greater clarity and dependability for every telephone user. But it is only one of many kinds of improvements that have been made.

The present generation does not remember the old days of the telephone. Service is now so efficient that you accept it as a matter of course. It seems as if it must always have been so. Yet it would be far different today if it were not for the formation and development of the Bell System.

Its plan of centralized research, manufacture and administration—with localized operation—has given America the best telephone service in the world.

AND THEN HE BOUGHT PYREX WARE

Laboratory Workers

know that broken glassware means waste and expense, in equipment, chemicals and time. And they know, from universal testimony and from daily experience, that "PYREX" Ware is the most satisfactory.

And it is also the most economical, because it resists breakage. "PYREX" brand Laboratory Glass has the lowest co-efficient of expansion of any commercial glass—0.0000032—which makes it unequalled in its ability to withstand sudden changes of temperature.

Because of this fact it is possible to use heavier and therefore stronger construction, to resist breakage under accidental jars and jolts.

Its superior composition resists the corrosion of powerful chemicals and protects the purity of solutions.

These features mean economy and convenience to the chemist who standardizes on "PYREX" Ware.

BE SAFE! See that this trade-mark is reproduced exactly on every piece of apparatus you buy.

ACCURATE 60°

SCIENCE

Pyrex

MICROCHEMICAL

Glassware

- LABORATORY glassware for use in micro-chemical analysis is now available in "PYREX" Brand Glass. To assure the scientists of the best results, standardization of design is essential. "PYREX" Micro Chemical Glassware is standardized.

Designed in collaboration with leading experts in the field, "PYREX" Brand Micro Chemical Glassware will greatly facilitate the special technique employed in the accurate analysis of minute samples. It provides micro apparatus of high chemical stability; unequaled in heat resistance; and protected by the thorough annealing that is possible only in scientifically constructed lehrs. Selections of "PYREX" Micro Chemical Glassware and of "PYREX" Laboratory Glassware listed in Part I of our general catalog may be combined to secure consumer's quantity discounts. Mail the coupon and get your copy of "PYREX Micro Chemical Glassware".

"PYREX" is a registered trade-mark and indicates manufacture by

CANNED FOODS IN INFANT NUTRITION

I. Evaporated Milk

No phase of human nutrition has been more intensively studied than has that of infant nutrition. As a result of numerous investigations, much valuable information concerning the nutritive requirements of infancy has been accumulated. In addition, the quantitative nutritive demands of early life have been established within reasonable limits.

Along with advances in our knowledge of the science of nutrition have come changes in the older ideas concerning infant feeding. It is now an accepted fact that properly modified cow's milk can successfully supplement breast milk—in fact, where necessity or expediency demands, cow's milk properly modified and properly supplemented, can meet

fully all nutritive requirements of infancy. As far as proper nutrition is concerned, the "bottled baby" of today starts on life's road with brighter prospects than did his fellow-being of a generation ago.

Evaporated milk is particularly well adapted to preparation of milk formulas for infant feeding. Numerous studies, laboratory and clinical, have demonstrated its nutritive values—ample practical medical experience has proven its worth in infant nutrition. From the wealth of available literature, we have selected the following concise summary which describes this canned food and outlines those characteristics by virtue of which it is held in such high esteem as an infant food (1).

(1) J. Am. Med. Assn. 97, 1890 (1931)

1. Evaporated milk is pure fresh cow's milk with approximately 60 per cent of the water removed by evaporation under reduced pressure.

2. Evaporated milk is equal to pasteurized milk in all important food values; it supplies those vitamins which milk can be depended on to supply and in practically equal quantity.

3. Evaporated milk is sterile and therefore is the safest milk obtainable; it cannot introduce pathogenic micro-organisms to induce diarrhea in infants.

4. Evaporated milk casein curd in the stomach has a finer granular and softer texture or structure than that produced from raw or pasteurized milk; it resembles in physical structure the curd of human milk.

5. The fat of evaporated milk because of the homogenization processing is more finely dispersed than the fat of ordinary milk and therefore it is more readily acted on by digestive enzymes.

6. Evaporated milk is more speedily digested than raw or pasteurized milk or milk boiled only a very short time.

7. Evaporated milk is usually less allergenic than raw or pasteurized milk.

8. Evaporated milk is one of the most convenient and economical forms of milk for preparing infant feeding formulas.

9. Evaporated milk enables introduction of more milk in the diet because it is concentrated.

10. Evaporated milk is considered by many pediatricians to be the best form of cow's milk for preparing the baby's formula.

The Seal of Acceptance denotes that the statements in this advertisement are acceptable to the Committee on Foods of the American Medical Association.

LIFETIME RED

A *New* PERMANENT LEGIBLE MARKING

FOR PYREX^{brand} GRADUATED WARE . . . LIFETIME RED—with a proved permanent legibil-

ity, as demonstrated in "PYREX" Red Lettered Reagent Bottles since 1932—is now available in "PYREX" Graduated Ware.

The scale and figures are etched through a red layer into clear glass and no filler is necessary. They stand out clearly against a broad band of Lifetime Red to give superior legibility, unlike any other design, method or material applied to marking laboratory glassware.

Lifetime Red is permanent. It is in the glass—a part of the glass—as enduring as the glass itself. No change in color or glass characteristics are discernible after these tests:

1. Exposure to steam at 100 lb. pressure for 360 hours (autoclaving test).
2. Thermal shock tests up to the limit "PYREX" apparatus is designed to withstand.
3. Solubility tests usually applied to "PYREX" Brand Glass.
4. Exposure to ultra-violet rays equivalent to more than 1000 years at the earth's surface.

The five items illustrated may be obtained from laboratory ware supply dealers throughout the country. Other items are under consideration.

No change is made in catalog prices, discounts, or package quantities—just specify Lifetime Red by catalog number shown below items illustrated.

*"It's great
to be
busy"*

"I'M A telephone installer and I like to be busy. A good many people are calling up these days and saying they would like to have a telephone put in.

"Often they will make an appointment and it's my job to be there on the dot. The company is a stickler for that. More than 97% of the appointments made with subscribers are now met at the exact time requested. We're trying to do even better than that.

"Seems to me it's something worth while—putting in a telephone. People always seem happier when I tell them

they are connected and everything is O.K. Especially if they have been without the telephone for a little while. Most everybody says the same thing — 'We missed it.'

"Well, I hope it keeps up. It means a lot to have a telephone in the house and it means a lot to us fellows who work for the telephone company."

The Bell System employs a total of 270,000 men and women. They are your friends and neighbors. Good business for the telephone company is a sign of prosperity in the country.

WHEN you specify Kimble Blue Line Exax Valumetric Flasks, you can be assured that nothing finer, nothing more accurate, nothing higher in quality and refinements is produced in a piece of technical glassware. Blue Line Exax flasks are made from blanks carefully selected to eliminate blisters, stones and streaks. The walls are heavy enough to resist the shocks of daily service. Bottoms are wide enough to stand (unstapped) on a 15° slope without tipping—a requirement of the National Bureau of Standards.

All lines and numbers are deeply acid-etched and filled with a brilliant and durable BLUE GLASS, fused in. Every flask—from the 10 ml. to the 2000 ml. size—is calibrated at 20° C. and RETESTED and RETEMPERED (strain-free).

Stoppers and necks are carefully ground to a leak-proof fit, and flasks and stoppers sandblasted with corresponding serial numbers. These flasks are guaranteed to the following tolerances:

Size	Calibrated to Contain	Calibrated to Deliver
10 ml.	±0.06 ml.	±0.10 ml.
25 ml.	0.06 ml.	0.10 ml.
50 ml.	0.10 ml.	0.20 ml.
100 ml.	0.16 ml.	0.30 ml.
200 ml.	0.20 ml.	0.40 ml.
250 ml.	0.24 ml.	0.50 ml.
500 ml.	0.30 ml.	0.60 ml.
1000 ml.	0.60 ml.	1.00 ml.
2000 ml.	1.00 ml.	2.00 ml.

Blue Line Exax Flasks—as well as a full line of Kimble Laboratory Glassware—are stocked by Laboratory Supply Houses throughout the United States and Canada. For the sake of assured accuracy and service, SPECIFY EXAX.

LIFETIME RED

Lifetime-Red Graduated Ware has a permanent red background which is an integral part of the glass itself. The graduation marks are etched through this permanent background and will remain legible and useful throughout its life.

The permanence of this background has been proven by four years of actual use on our Red Lettered Reagent Bottles. There has been no discernible change in color after such tests as 360 hours at 100 lb. steam pressure in autoclave.

At present this ware is only available in five items.

There is no change in catalog prices:

Cat. No. 1310-R—100 ml Graduated Cylinder.

Cat. No. 1790-R—250 ml Volumetric Flask.

Cat. No. 2120-R—Folin-Wu Urea Tube.

Cat. No. 2150-R—15 ml Graduated Centrifuge Tube.

Cat. No. 2165-R—100 ml Oil Centrifuge Tube.

The HIGHLIGHT
OF EVERY MEAL

KNOX SCIENTIFIC FACTS

Every batch of
Knox Gelatine
undergoes ultra-
microscopic tests
for clarity.

Analysis

Knox Gelatine

Protein (14 amino acids)	85.0—86.0%
Calcium Phosphate	1.0—1.25%
Fat (less than)	0.1%
Moisture	13.0—14.0%
Carbohydrate	Nil

Of interest in the
treatment of muscular
dystrophy is the
25% glycine (ami-
no-acetic acid) in
Knox Gelatine.

Bacteriologically
safe... almost neu-
tral pH... odorless
... free from carbo-
hydrates... exceeds
in quality minimum
U. S. P. standards.

In Gastric Ulcer GELATINE U.S.P.

A Non-Irritant Soft Food

IN Gelatine U.S.P., the gastric ulcer patient has a nu-
tritious food which is compatible with his restricted
diet, congenial to his taste and welcome in the tempting
variety of appetizing dishes which it affords.

Knox Sparkling Gelatine surpasses in all respects the
minimum U.S.P. standards of purity. Its fine texture
and rapid solubility promote prompt assimilation, with
an absence of irritation to inflamed mucosa. It soothes
and aids healing.

Prescribed diets can safely utilize the added protein
content of Knox Gelatine for the convalescent, tubercu-
lous, diabetic or post-operative patient. Quite a re-
markable product—Knox Gelatine... made as care-
fully as an ampule solution.

Number 1

Concern of the United States with Tropical Diseases*

F. W. O'CONNOR, M.R.C.S.

*Department of Medicine, Presbyterian Hospital, Columbia University,
New York, N. Y.*

OUR responsibility regarding tropical diseases requires consideration of various factors. Of primary interest to us are the diseases of the mainland, but we must also consider those of our various dependencies and protectorates, and of the army and the navy whose members may serve in any part of the world. We have, furthermore, a measure of responsibility for the many commercial enterprises having branches in foreign countries and for the engineering, scientific, and missionary organizations whose work is largely carried on in foreign fields. Viewing the matter from this broad standpoint it will be readily appreciated that our concern with tropical and imported diseases is national.

Most of us know that the diseases referred to have played an important part in the development of this country from its earliest days, and it is therefore desirable to review this aspect of the subject. Many of these diseases are still of serious importance to us, and we have to consider their possible influence

on the future of the people as well as our ability to control them.

According to the earliest records the first white settlers found this a healthy country, and there is no suggestion that they were affected by tropical diseases on their arrival. This happy state, however, was of short duration, and we learn of malaria having been introduced by the Spaniards at an early date. With the establishment of the slave trade the African brought not only this infection but many others. Those infections which required no intermediary host for transmission, such as hookworm, ascaris, etc., as well as those which found a suitable insect host, for instance the virus of yellow fever, the plasmodia of malaria and *Wuchereria bancrofti*, established themselves on the mainland. On the other hand the trypanosoma, schistosoma, loa loa, as well as other less important parasites, in the absence of a suitable host, could not spread in North America. *Malaria* spread rapidly and Rush tells us that remittent and intermittent fevers were responsible for a high mortality and much invalidism. In some localities he found that scarcely a family, and in some families scarcely a

* Read at a General Session of the American Public Health Association at the Sixty-third Annual Meeting in Pasadena, Calif., September 4, 1934.

member, escaped the disease. Later, in his lecture courses Hosack considered malaria so important that he devoted 3 lectures to this subject alone. La Roche in 1855 stressed the prevalence of the infection on the outskirts of developing settlements. During the Civil War Woodward states that there were 1,213,685 cases of malaria with 12,199 deaths among the Northern troops, and adds that it was even more prevalent among the Confederates. Vaughan, in writing about his experiences in 1865 says, "Every man, woman and child in southern Illinois, at least within my range, shook with ague every other day"; and later, "That summer I saw enough of a people held in bondage with malaria to make a lasting impression on a boy's mind."

Hirsh in 1883 found that the largest foci of infection in the United States were on the shores of the Great Lakes and particularly in the southern part of Michigan. He reports pernicious attacks of the disease at Detroit and Plymouth, and as far north as Hamilton and Kingston, in Canada. It was then endemic in the northeastern part of New York, but he adds, "It is mostly along the banks of the Hudson and on a narrow strip of coast that the disease is endemic in this state." According to Ferrell, in 1881 the death rate from malaria amounted to 4.2 per 10,000 of population, and only in 1890 did the mortality fall below 1 per 10,000 in New York State. Not until 1898 was the mortality less than 1 per 10,000 in New Jersey; and in Indiana the rate was 1 per 10,000 prior to 1900.

Yellow fever appeared first in Boston in 1692, introduced from the West Indies. In 1699, only 17 years after the founding of the city, it spread havoc in Philadelphia. From that time until 1853 in cities ranging from Providence, Rhode Island, to New Orleans, La., epidemics of varying severity caused high mortality. Subsequently smaller out-

breaks occurred at Decatur, Ala., and elsewhere, but with the exception of a few laboratory infections the disease has not appeared in this country within recent years. Philadelphia especially suffered during the epidemics. From Philadelphia physicians of that time we have excellent accounts of the disease as well as references to the outbreaks of malaria and dysentery which usually preceded the epidemics.

Dysentery is frequently described by the early American writers. Both febrile (bacillary) and afebrile (probably amebic) are mentioned. Woodward's figures for acute and chronic diarrhea and dysentery for the Civil War period are 1,739,135 cases with 44,558 deaths. This writer gives good accounts of hepatic abscess, which, single or multiple, was found in 1 out of 25 autopsies of diarrheal or dysenteric cases. This disease was not limited to armies, for Vaughan tells us that "the most fatal childhood disease is designated in the family records as 'bloody flux' . . . It is a bacterial dysentery and in some generations has killed half of the family, mostly before they reached 5 years of age." Large or small outbreaks of bacillary dysentery have occurred in different states since the time Vaughan refers to and within the last 6 weeks we have heard of its presence in Jersey City, New York, and Boston.

Cholera—Three severe visitations of cholera have reached the United States. In 1832 the infection having entered through Canada spread to Detroit, New York, Pennsylvania, Maryland, Virginia, and Kentucky and along the Ohio River to Indiana and Illinois. In October of that year it was severe in New Orleans whence it spread along the Mississippi. In 1848 cholera started in this country at New York and New Orleans. From the latter city it reached Memphis and Texas. In 1849 it spread over the whole of the country

east of the Rocky Mountains and in 1850 it was widespread in the far west and in the basins of the Mississippi and Ohio Rivers. Cases of cholera were present in certain parts of the country until 1854. The last serious epidemic of this disease arrived from Halifax in 1866. It appeared in New York and New Orleans and spread throughout the country with the exception of the states along the Atlantic seaboard.

Dengue has appeared frequently in this country and is endemic in certain areas of the South. The first epidemic of which we have a fairly clear account was described by Rush in 1780. There was a widespread epidemic in the South in 1850 and another in 1924 which spread from Texas to North Carolina. In the last available *Public Health Reports* cases of dengue are reported for 1931 and 1932, and only a month ago an outbreak of some local importance was reported in Miami, Fla.

Relapsing fever was brought to this country at an early date by immigrants from Europe. According to Craig it was first recognized in the United States in 1846. Parry mentions the disease as being present in New York and Philadelphia, and describes an outbreak in the latter in the winter of 1869-1870, when he had 37 cases in his own practice. The disease has since been reported in different parts of the United States and Canada. Most of the earliest outbreaks were probably transmitted by lice. Recently the disease has been found to be endemic in Texas and California, where the transmitting agent is believed to be a tick, belonging to the genus *Ornithodoros*.

Leprosy was introduced both from Europe and from Africa. It was not uncommon in the Mississippi Valley 150 years ago (Denny). In 1872 it was found to be spreading among persons of French descent in the South, and an endemic area exists on the coast of Texas northeast of Galveston.

Undulant fever was first recognized by Musser and Sailer in 1898, although in all probability it had been here for a long time. Those who have worked on this disease since, feel that possibly the epidemic of typhomalaria in 1880, as described by Hoff, was undulant fever. Craig saw many cases in the army in 1904. In 1918 it was found that *Brucella abortus* was frequently present in cows' milk in the San Francisco region. In 1922 there was a severe epidemic of this disease in Phoenix, Ariz. In the last available *Public Health Reports* 1,578 cases were reported for 1931 and 1,502 for 1932.

Doubtless many of the other tropical diseases with which we are familiar existed from the early settlement of the country but they were not understood. From historical record therefore we learn that tropical diseases were a serious menace to the pioneers of this country during its early development, and that most of these diseases were imported. Most important among the lessons of this experience is the fact that with economic improvement in a people's condition and with the increasingly efficient public health service which such improvement renders possible, most of the diseases, called tropical, may be kept within the limits of their more usual climatic zones.

While we may reasonably hope that epidemics of the more destructive tropical diseases, such as cholera, yellow fever, and plague, are unlikely to afflict us in the future, there are abundant reasons why we should take thought of the many others which still exist in this country.

Strangely enough, at the present time there is a greater variety of so-called tropical diseases in the United States, and a higher incidence of some of them, than is found in the European countries where the same diseases are indigenous. The most important contributing factor is the vastness of this

country, which includes a sub-arctic, a temperate, and a sub-tropical climate. The varying topography of the different states also exercises an influence. Furthermore there are no sea barriers between the tropics and the temperate zone as there are in Europe. Such barriers have undoubtedly prevented the spread of certain infections there, whereas we have none between Mexico, Central America, the southern states, and the remainder of North America. We have also a constant influx of our own citizens from Puerto Rico on the east coast and from the Philippines on the West Coast, in addition to which there is a large immigrant population from the Caribbean Islands, Central and South America, which settles primarily in the large cities of the Atlantic seaboard bringing their parasites with them. I know nothing of the incidence of animal parasites among the resident population of Orientals on the west coast but, judging from experience in New York with Chinese clinic patients, the incidence of hookworm, ascaris, whip worm, and the Oriental liver flukes must be fairly high. Due to our extensive coastline, with some ports in the sub-tropical zone, many persons from the nearby tropics come to this country on business or for study or medical consultation. As a result of these different factors we find in the large cities a variety of parasitic and tropical conditions which is unique for a more or less temperate climate. While it may be said that within this country everything possible is being done to combat the more serious tropical diseases, we should consider whether we are not neglecting the dangers of some imported infections. A fair percentage of the immigrants or citizens who come to our large ports eventually settle in rural districts where sanitation is as primitive as in their country of origin. One wonders if it would not be well to include in the medical examina-

tion which is given to immigrant aliens on entry, at least one stool and blood examination, to obviate as far as possible the likelihood of their supplementing the parasitic conditions already found in the United States and Canada which it is our object to suppress.

While it is impossible to classify these infections according to their geographical limits in the states, it is possible to place them in categories according to their prevalence. Thus undulant fever, the intestinal protozoa, trichiniasis, *T. echinococcus*, *T. saginata*, *Enterobius vermicularis*, and some skin infections, and snake bite (except in Maine), may be found fairly frequently, or may occur in sporadic instances in most states of the Union. On the other hand, malaria, blackwater fever, hookworm, pellagra, ascaris infection, leprosy, relapsing fever, dengue, granuloma inguinale, climatic bubo, endemic typhus or Brill's disease, hymenolepsis nana infection, creeping eruption, filariasis (limited to Charleston, S. C.), and rarer conditions such as madura foot and ainhum, are more prevalent in, although not strictly limited to the southern states.

Diphyllobothrium latum infection has of recent years become increasingly common in the northern states. Many of the fish in the Great Lakes district are infected, and Magath has given us very valuable information on the subject. Five years ago *T. saginata* was the most commonly encountered tapeworm at the Presbyterian Hospital, New York, whereas now it is outnumbered by the fish tapeworm. It is of interest to note that in our experience most of these infections occur in the female members of orthodox Jewish families. These people are the largest consumers of the fish which is shipped from the Great Lakes district.

While the majority of these conditions considered separately are not definitely of public health importance, collectively they are responsible for a

considerable degree of invalidism. Of particular importance, however, we may consider malaria, hookworm infection, pellagra, amebiasis, leprosy, and undulant fever, while relapsing fever and ascaris infection merit our attention as being potential menaces in certain areas.

Malaria continues to be a serious public health problem. The economic loss resulting from its effects is an important factor. Children are retarded both in their mental and physical development. Ferrell has shown that in 1919, 1920, and 1921, 520 counties in 16 states reported a mortality rate from malaria of more than 1 per 10,000 inhabitants. The percentage of counties in the respective states having a significant problem varied from 5 per cent in Kentucky to 90 in Mississippi, and the proportion of the states' population included in such counties ranged from 1 per cent in California to 92 in Mississippi. In Arkansas, Florida, Louisiana, and Mississippi, approximately three-fourths of the population live in counties having a malaria problem. In 1932 there were 68,613 reported cases of malaria from 37 states, with 2,625 deaths.

Considerable research has been devoted to the prevention of this infection. Where drainage is possible it is most efficacious. Filling in, as employed in land reclamation, has done much to limit its prevalence. Certain species of larvacidal fish have been found useful in some districts. Oiling of breeding waters has its advocates, and various chemicals have been used with some success. Of recent years a definite advance in the prevention of malaria has been made by treating the breeding places of anophelines with Paris green. In smaller collections of water the chemical may be disseminated by hand; in larger areas it is distributed by airplane. In many places where other measures are not practicable the

mosquito proofing of houses has proved efficacious. In all malarial areas the people should be advised when possible to use mosquito nets. Sometimes a combination of several of the methods mentioned may be necessary. The use of quinine as a prophylactic has been shown to be useless, but the sterilization of carriers of gametocytes with plasmochin may help to prevent infection of their fellows.

Medical officers of health should have special knowledge of the prevention of malaria along the lines referred to, and this necessitates a preliminary knowledge of the differentiation of mosquito genera and the morphology of eggs, larvae and adults of the anophelines which are the carriers of the plasmodia. It is important to recognize the kinds of water in which such anophelines breed. This varies in different localities. Some species breed in stagnant waters; others by the side of streams; some require the freshest water; others tolerate a fair degree of salinity.

Hookworm is a disease which has only been understood within comparatively recent times. In heavily infected persons it causes severe anemia and debility. The effects on children of school age are very apparent, for it produces stunting of growth and retardation of mental development. Valuable work has been done in this country on worm and egg counts, from which we have an index of the number of worms necessary to cause hookworm disease. However, it must be remembered that when associated with other infections such as tuberculosis, malaria, pellagra or amebiasis, much smaller numbers of hookworms may play a serious rôle in aggravating the severity of symptoms or retarding convalescence after any intercurrent sickness. Considerable progress has been made in combating the disease by means of education, sanitation, and by massed treatment. Jacocks describes hookworm surveys in

11 southern states in 1910-1915 and resurveys of the same areas in 1920-1923 following an active treatment campaign. In the original survey he found 51.1 per cent of the rural school children infected, whereas in the second, he found only 27.8 per cent, a reduction of 49.5 per cent. He points out that the reduction of the severity of the disease was probably much greater even than the figures would indicate. In Mississippi, Keller, Leathers, and Ricks, by massed treatment have reduced the infection 62 per cent in the period from 1910 to 1933. From these brilliant results states and counties with a hookworm problem have abundant assurance that if they carry out control measures on the lines that have been proved to be successful they may rid their population of this incapacitating infection, or at least reduce its incidence to that of negligible importance.

Pellagra—Since many cases of the food deficiency disease, pellagra, remain undiagnosed, it is probable that during any year the figures given for this disease are well below the fact, although the reported figures are sufficiently serious. It causes debility, anemia, gastrointestinal disturbances and insanity, and has a high mortality. Pellagra is so often associated with hookworm infection that the gastrointestinal symptoms are frequently attributed to the latter. This is certainly not the case since pellagra occurs with the same symptomatology in countries where hookworm does not exist, but, nevertheless, as a contributing factor hookworm infestation must be considered. It is significant that pellagra is especially prevalent and severe in those countries where there is a high incidence of hookworm, namely, in Egypt, and in our own southern states. The disease becomes more prevalent during periods of special privation. Goldberger's inquiries concerning pellagra in Tennessee, Arkansas, Mississippi, and Louisiana show that in

1924 there were 20,000 cases with 1,026 deaths, whereas in 1927, after the flood and its attendant want and privation, he estimated that there were 50,000 cases with 2,500 deaths. According to the last available *Public Health Reports* there were 15,643 cases in 19 states during 1932. The control of this scourge is largely dependent upon improvement in the economic condition of the people and upon their education along dietary lines.

Plague—With the exception of small outbreaks in Louisiana and California, plague has not assumed dangerous proportions in this country. The infection is indigenous among desert rodents in some parts of California, Montana, and Nevada, and cases of rodent plague are sometimes found about ports. From experience in India and other countries it is known that an increase in the incidence of rodent plague usually precedes the appearance of the first human cases; therefore, it is only by constant observation of rodent plague incidence that the disease can be prevented from appearing in epidemic form among human beings. That we have been protected against such visitations in this country is entirely due to the vigilance and efficiency of the health authorities.

Amebiasis—It is now generally recognized that amebiasis with its destructive complications is not limited to the tropics. The usual methods of transmission by flies and water from contaminated streams and wells are such that man probably gets only a small infection at one time. He is thus able to build up some immunity so that with the onset of the disease the symptoms are usually insidious or mild. For this reason also the disease has been known as an endemic one. However the recent epidemic in Chicago indicates that we must modify our original conception of the transmission of this disease, and that in this, as in typhoid and bacillary dysentery, the very effort toward the

better sanitary protection of mankind may not only bring new evils in its train, but may also upset the usual biological balance between parasite and man. Epidemiological evidence suggested, and the sanitary engineers have demonstrated, that this epidemic was caused by the massed contamination of potable water with sewage containing *E. histolytica* cysts, mainly in 2 hotels. As a consequence, many persons with no acquired immunity became heavily infected and probably reinfected within a short space of time, with the most serious consequences. It is at least probable that the contaminating agency was associated with infringements of established rules and laws regarding cross-connections. In the past we have had outbreaks of bacillary dysentery due to contamination of water resulting from cross-connections and faulty plumbing, and since we now have evidence of another disease being transmitted in the same way, it is most important that inspection of our hotel and residence water systems should be carefully and systematically undertaken by properly qualified sanitary inspectors. The Chicago epidemic of 1933 is a warning to all municipalities and health officers that under conditions of "guest strain" during conferences, expositions, pilgrimages, etc., another such epidemic might easily occur in any large city. *Entamoeba histolytica* cysts exist in 5 to 10 per cent of the population. Each infected individual is in danger, should his physiological balance break down, and he is an especial menace to his fellows under conditions such as existed in Chicago. Health authorities should be alert to the significance of this infection, especially when it is known that several members of a family or small groups of persons in limited localities are infected. The Chicago epidemic also showed the limitations of physicians in recognizing the condition.

From personal experience it is also

clear that the clinical knowledge of physicians is equally limited concerning other grave diseases, which though more common in the tropics are fairly prevalent among us. Therefore, while it does not seem indicated to add to the already crowded curriculum of the medical student, he should be advised to have a reading knowledge of most tropical diseases, and more emphasis should be given in his medical course to malaria, hookworm, amebiasis, and undulant fever in their clinical and laboratory aspects. This is even more necessary for the medical student of the South.

For physicians desirous of becoming medical officers of health much more knowledge is required in this branch of medicine, especially regarding insect-borne diseases and the large group disseminated by fecal contamination. With regard to the former he should not only be able to recognize the insects themselves but should understand the bionomics, the methods by which they become infected from man, and the duration and nature of the development of parasites within them under varying climatic conditions. For those conditions transmitted through feces further knowledge is necessary, such as the conditions under which embryos develop inside the egg, whether they remain in the egg, or, if they hatch, to what extent the surrounding soil may become contaminated, the methods of infection of man for each parasite, the conditions by which flies act as porters of parasites, and the various ways by which water may be contaminated in wells, streams, and from reservoirs to water mains in buildings.

A knowledge of general measures known to be effective in the prevention of parasitic diseases transmitted by fecal contamination is also of importance. *Enterobius vermicularis* or pin-worm, ascaris, and the tapeworm, *Hymenolepis nana*, are directly trans-

mitted from material contaminated with feces by the fingers to the mouth. Hookworm larvae hatching from the egg on the ground enter the skin of the feet, hands or buttocks when in contact with them. The intestinal protozoa are transmitted by flies or by the water of wells or streams which have been contaminated by feces. The essential points in the prevention of all these infections is the education, especially of children in schools, to the dangers of such methods of infection, and of the vital necessity of personal cleanliness following defecation and the proper disposal of excreta within the limits of economic ability. Regarding towns and cities, the sanitary inspection of reservoirs and other water supplies at their source is not enough; a rigid inspection all the way from the source to the consumer is most important.

Leprosy is a public health problem in every country where it occurs. It was probably more prevalent in this country formerly than it is at present, but even now as the official figures show it is fairly common in the southern states. Happily, owing to the more humane method of caring for lepers, there is less tendency on the part of these unfortunates to try to hide their condition, and the danger of spreading this disease is proportionately limited. In the South the lepers are willing to avail themselves of the help offered them at the Federal Leper Colony in Louisiana. The concern of the United States with leprosy is of great importance in her colonies. The institutions for lepers in this country, in the Philippines, in Hawaii, and in Puerto Rico, and the Leonard Wood Memorial have earned a world-wide reputation for their work on the control and treatment of this disease.

Experience in our clinic suggests that there is a high incidence of infestation with the round worm, *Ascaris lumbricoides*, in this country. It is therefore

interesting to learn from Cort and Otto that no endemic centers of this infestation of public health importance are reported from the northern and western parts of the country. The real problem is among the indigenous population of the Appalachian Mountains and the foothills running south, east, and west from this range, especially in Kentucky where the incidence is highest. Outside the mountain area important foci were found in Columbus County, N. C., in south central Louisiana, and in the city of Tampa, Fla. At the last the incidence is highest among the Cubans and their American born children. It is interesting to note in this connection that Boeck and Stiles found 21.9 per cent of 196 newly arrived immigrants, mainly from southern Europe, infested with ascaris, and that Cort reported 2.5 per cent as positives in 507 Japanese laborers in the delta region of central California. In New York we have found several ascaris families among missionaries recently returned to this country.

Ascaris is notorious owing to the frequency of serious accidents due to its wanderings from its usual habitat, the small intestine of man, into various parts of the body, and to the obstructions which it may cause through numbers. Moreover it is commonly associated with a variety of gastrointestinal and nervous symptoms, while mental phenomena may sometimes occur. In children with heavy infestations mental and physical development may be retarded, and, following early after infestation, during the wanderings of the embryo through the lungs, symptoms varying from bronchitis to pneumonia may develop.

Infestation is direct by mouth owing to ingestion of ova containing embryos which have matured on the ground where feces have been deposited in damp, dark, and warm places. It is therefore most prevalent in sections where sanitation is primitive or absent. In such places children are liable to

defecate in the region of the doorway or porch. Children show a higher incidence than adults. Frequently whole families are infested and are known as ascaris families. They are a particular menace, and act as distributing foci to neighboring families and at such rural schools as have no sanitary facilities. Prevention of this infestation depends upon the installation of suitable privies, and the education of the people regarding ascaris, especially through the children at schools which are situated in areas of high incidence. Special attention should be paid to the treatment of ascaris families to prevent dissemination.

From clinical and pathological observations in New York it is clear that *T. echinococcus* or hydatid infection and trichiniasis are by no means uncommon in some parts of this country, but we neither have records of their incidence nor do we know how much of these infections are imported. It would be both important and of general interest to have information on these matters.

Tularemia and Rocky Mountain spotted fever have found their way into the textbooks on tropical medicine without reason. Psittacosis has caused some interest of late, and has given us some reason for uneasiness. Happily the response to the need for research and prompt measures of prevention with education of the public have done much to prevent the spread of this disease.

The scientific contributions of our forebears and contemporaries give some indication of the importance of tropical disease to this continent. Significant as have been discoveries in medicine in other fields, in none of them has the output been so large on the one hand and so beneficial to all peoples on the other. The record is a splendid one and would provide abundant material for a volume on the history of tropical medicine in North America. On such an occasion as this, only mention of the

most outstanding achievement is possible, such as the Army Commission headed by Reed on the transmission of yellow fever, Gorgas's control of yellow fever in Cuba, and of both malaria and yellow fever in Panama, making possible the construction of the Panama Canal, Ashford's investigations on hookworm, Goldberger's work on the etiology and prevention of pellagra, a succession of brilliant contributions on amebiasis by Leidy, Walker, and Sellards, Musgrave and Clegg. Siler's work on the transmission of dengue, Vedder's on emetine and beri-beri, McCoy's on leprosy, and of McCoy and Francis on tularemia, and the many outstanding contributions by officers of the U. S. Public Health Service on undulant fever, leprosy, and pellagra. Much of the work on the culture of parasites originated in this country. Novy was pioneer in the culture of the leishmania, Bass was the first to culture the malaria parasite, and Boeck the first able to cultivate successfully the parasitic amebae of man. Noguchi's work on the leishmania, the spirochetes, and *Verruga peruviana* was not the least of that scientist's contributions. Flexner's contribution on bacillary dysentery, Brill's on endemic typhus, and that of Louise Pierce on tryparsamide are also outstanding. The manner in which the Rockefeller Foundation blazed the trail in the control of hookworm, malaria, and yellow fever will make an epic in medical history. The memory of many other discoveries too numerous to mention, though of great importance, will endure. Such a record fills us with admiration but it gives us no right to be content.

Unfortunately, time will not permit the discussion of many unmentioned phases in the field of tropical medicine, but I hope that I have shown that as tropical disease was of vital concern to the pioneers of this country, so now there are many reasons why we should be on our guard, due to the greater

proximity of the tropics resulting from the more rapid modern transportation by ships of the sea and air. At present there is no cause for alarm regarding the spread of these diseases, although we may well be warned by the recent Chicago outbreak of dysentery. Just as we have conquered some epidemic diseases, such as cholera and yellow fever, and have reduced the range and prevalence of others, such as malaria and hookworm, so in the future we may hope that serious tropical disease may become

less of a public health problem, while those who follow us may see some of these diseases banished from the land as we have seen yellow fever disappear from the member nations of this Association. This optimistic view presupposes that there will be no relaxation of vigilance or effort on the part of physicians and sanitarians, both in the research they may undertake and perhaps, most important of all, in the education of the public in the special health problems of tropical diseases.

Physical Examinations of Young Workers in Belgium

PHYSICAL examination of industrial workers under 18 in Belgium is the subject of a recent official report. Such examinations, introduced by a decree of 1920, are given at the time the young worker is admitted to work, and thereafter annually, and if the physician finds that the young worker's health is unsatisfactory, more frequently.

The employers are required by law to coöperate in this work; they must keep a register of all workers under 18, report to the physicians the names of new workers and of those who are frequently absent by reason of illness, and follow the recommendations made by the physicians with regard to workers whose health is unsatisfactory.

The examinations are performed either by medical inspectors employed by the government, or by private physicians paid by the employers and supervised by the medical inspectors. The results of the examinations are noted on individual cards, which are

kept either by the physician in his office or at the establishment. The information is not accessible even to the employer.

The young worker and his parents are informed about any condition that needs correction. No treatment is given by the examining physician, but the boy or girl is referred to the appropriate social welfare agency, where the necessary medical attention is given. The examining physicians with the aid of nurses and personnel workers are active in finding suitable work for those in need of special care.

During the 12 year period between 1921 and 1932 over 610,000 boys and girls were given examinations upon their admission to work in industrial establishments—all the larger establishments and some of the smaller ones; 9 per cent of these workers were found to have defects requiring additional examinations. — *Revue du Travail*, Brussels, No. 7, 1934.

Civil Works Administration Emergency Relief Administration Malaria Control Program in the South *

LOUIS L. WILLIAMS, JR., M.D.

Surgeon, U. S. Public Health Service, Washington, D. C.

IN the spring of 1933 the Federal Emergency Relief Administration was organized. Some of the state health departments immediately utilized relief labor on their malaria control projects. In October the Civil Works Administration was organized and announced that it was searching for worthy projects on which CWA laborers might be given gainful employment. The Public Health Service submitted to them a program for antimalaria drainage. This was enthusiastically incorporated in the CWA program and an organization for its administration was set up in November, actual work commencing in December, 1933.

On such short notice it was not possible to organize technical supervisory forces in 14 states, from resources within the state health departments, with which to direct the large number of laborers who must be put to work quickly. The Public Health Service was asked to supply this technical supervision for the drainage work and was given \$350,000 of PWA funds through the CWA.

The organization within each state consisted of a state director of malaria control to assist the state health officer;

district supervisors, whose number was based upon expected federal allotment of labor; and local supervisors. The federal allotment was greatly augmented, as nearly every state far exceeded the federal quota of drainage laborers. The assistant state directors and the district supervisors, working with and under the state boards of health, made surveys as rapidly as possible in order to find the most worthwhile projects; secured approval of projects; trained local foremen; received the labor and put it to work.

State records defining the malarious areas of each state, physicians' reports, hearsay evidence, and population densities, have defined the limits of each project. As was to be expected, there were frequent requests from influential landowners who sought free drainage where no particular malaria problem was involved. Fortunately, these were for the most part detected, and failed to get approval.

There were, in spite of the hurriedness of the entire relief organization, 14 assistant state directors with their 59 district supervisors, and 212 local supervisors, at work before the end of December. For nearly 4 months they supervised an average of 64,000 workers, the peak week accounting for 120,000 laborers. Nearly 6,000 miles of ditch were dug, draining 100,000 acres

* Read before the Third Annual Meeting of the Southern Branch A.P.H.A. in San Antonio, Tex., Nov. 13, 1934.

of pond and more than 200,000 acres of swamp, affecting an adjacent population estimated at 8,000,000 persons. As it was not known how long relief labor would be available, state and district supervisors were urged to secure a promise from local authorities that necessary maintenance would be financed should the relief be suddenly withdrawn. In addition, educational campaigns for the purpose of popularizing the work were initiated to insure its future maintenance. CWA work is at present being maintained in most instances, and probably will be as long as relief labor is forthcoming.

The CWA came to an abrupt close at the end of March, 1934; so the malaria control project was continued under the Emergency Relief Administration. The immediate change in policy stopped most of the drainage work and a number of weeks passed before its continuance was assured under the various state relief administrations. Before the end of May most of the states were continuing the work.

Under the ERA there were 15 assistant state directors with the number of district supervisors reduced to 50, and only 7 local supervisors. However, this policy change from a work project to a relief project with its slower growth led to better planning of each project and, in the main, work was better done than under the hurried CWA. To date nearly all CWA projects have been completed and most of the remainder will be finished before the end of December, 1934. This does not apply to a few very large projects which have been undertaken on the theory that relief labor (certainly in some places) will be available for 2, 3, or 4 years more. During the last 6 months of the Emergency Relief operations, approximately 2,000 miles of additional ditch have been dug, draining over 16,000 acres of ponds and somewhat more than 30,000 acres of swamp, affecting an adjacent popula-

tion of 2,000,000 persons. In places where drainage is not at present feasible some home screening projects have been undertaken. In a number of cases definite contract has been secured from local administrations that maintenance work will be locally financed when relief labor is no longer available.

The trend of malaria in the United States has been steadily downward for 70 or more years. The actual decline has fluctuated to some extent. The periodicity of its fluctuation, however, could not be accurately worked out, for usable records were not kept prior to 20 years ago. The records of the last 14 years show that the falling rate curve flattened out about 1919 with somewhat of a rise in 1920 and 1921, and then a resumption of the decline. The curve flattened out again in 1926 and showed a definite rise in 1927 and 1928, subsequently falling as before. The curve flattened out in 1932 and rose a little in 1933, and indications are that during the summer season of 1934 there has been a very sharp rise.

The decline in the malaria rate has been accompanied by a recession of the northern limit of the malaria territory; and also has shown a lessening of the virulence of the disease. Each rise in the rate has been accompanied by a reinvasion of a small portion of territory formerly malarious; by an increase in the virulence; and by local epidemics. The rise of 1934 indicates a rate higher than any during the last 20 years, for one or more definite epidemics of malaria have appeared during the fall in 7 states, 3 of which are states that have been at the northern limits of endemic malaria, and 1 of which has been entirely out of the malaria column for over 10 years. Also, the northern limit of malarious territory has moved north many miles and the virulence of the disease is greater than it has been for over 20 years. It is a matter of considerable interest and significance that the reports

so far available indicate that the increases in malaria have not occurred where Emergency Relief projects have been completed. It is not difficult to imagine the situation had not the hazard of malaria been removed from the bulk of the 10,000,000 people adjacent to these projects.

I do not mean to paint an ideal picture of perfect work perfectly carried out. Many projects during their inception were improperly planned by supervisors of limited experience and some even were constructed where work was unnecessary. Here and there ditches appeared that were almost impossible to maintain. However, most of these errors were corrected, and those few remaining are on the program for proper reconstruction. The estimates of our most experienced men in the field who have visited a large number of projects indicate that at least 90 per cent of the work has been good work and that, at a maximum, not over 10 per cent can be classed as poor. Lack of maintenance has created some new impoundings where loops of old streams, left open, have filled with backwater, or where uprooted trees have clogged main ditches. Some winter-dug ditches constructed by untrained personnel have very wide, flat bottoms. During the summer there has been insufficient water to maintain a continuous flow so ponds have appeared in territory

hitherto lacking in ponds. Here and there, particularly in the earlier ditching, there are large spoil banks too close to the edge of the ditches. Occasionally there can be found a ditch, through a swamp, with no laterals tapping deeper pools near the outer edges. These very errors were in themselves educational. The engineers and foremen, observing the operation of the poorly constructed ditches, seldom repeated the errors. These experiences have not only educated supervisors, engineers, and foremen, but also thousands of laborers throughout the South. This, in addition to the educational program, has gone a long way toward teaching the bulk of the population in the malarious areas to recognize good drainage and presages future control.

In addition to the drainage projects a blood index was taken to determine the endemic rate of malaria in the 15 states. To date, 129,000 slides have been examined. Unfortunately, the slides could be taken only while the CWA was in force and therefore were secured only in the winter and very early spring. At that part of the year the reservoir of malaria is at its lowest. The 129,000 slides show an infection rate of 5.8 per cent. This is divided into nearly 60 per cent benign tertian and 40 per cent estivo autumnal. There is a scattering of quartan—less than half of 1 per cent. In one state an in-

* Index report only of number of slides examined through October, 1934. Over 50,000 stained slides yet to be examined.

dex in the summer shows an infection rate among adults of 10 per cent. A number of localities experiencing severe malaria outbreaks recently have shown rates from 50 to 65 per cent. In our former studies fall rates of 18 per cent to 26 per cent have not been at all unusual. A number of such areas on recent resurvey have exceeded 30 per cent. The 10,000,000 persons adjacent to drainage projects were known to harbor malaria parasites at the rate of 5.8 per cent during the winter—what the rate would have been this fall without the control work it is impossible to say, but a conservative estimate places it at not less than three times that figure. At least one can say

that the benefits have been considerable.

If the present program can continue, the ultimate benefits to the South are incalculable. Maintenance of the work and extension into new territory is assured as long as ERA labor is available and is provided with adequate supervision. The Public Health Service has nearly exhausted the fund allocated to it for supervision, so if direction through the State Boards of Health is not forthcoming we may confidently expect to see ERA labor placed on other projects. The immediate concern of each southern state health department is to devise at once a workable plan that will assure continuation of expert supervision.

Effects of Depression on the Vision of Children

SCANT attention has been given in this country to the manifestations of disease of the eyes following long periods of dietary insufficiency and imbalance in a large group of our populace during the present depression. It has been assumed that though these diseases may be found in China, and were to be found in Germany during the war, this country has escaped them during the present depression.

Unfortunately, as a result of the long depression and consequently poverty, these diseases are beginning to appear in this country. Totally inadequate or imbalanced diets of the unemployed are beginning to exact their toll. Among the children of New York City, particularly in certain sections of the community, I have noted increasing incidence of pathology of the eye of this nature.

Disease of the eye due to diets deficient in vitamin A content is becoming far less rare than it used to be considered; I was almost impelled to say, are becoming fairly common. Xeroph-

themia of a mild form and hemeralopia (day-blindness) are not at all uncommon. I have noted that in quite a number of children proper refractive correction failed to give a satisfactory improvement of vision, in the absence of gross pathology; that vision findings with the same correction were better on dull and cloudy days than on bright, sunny days; and finally that placing these children in a dark room for 10 minutes to a half an hour resulted in a sharp rise in vision, and exposure to bright light caused a rapid drop in visual acuity. These cases rapidly respond to vitamin A therapy in the form of caritol, cod-liver oil, and a diet incorporating raw carrots, with a sharp rise in vision. Some of the more long-standing cases, however, present corneal changes which are less promising in prognosis for vision. Pigmentary changes are especially prominent in negro children. . . . E. M. Josephson, M.D. *The Eye, Ear, Nose and Throat Monthly*, Dec., 1934.

Report of Special School Health Studies in New York City*

DONALD B. ARMSTRONG, M.D., Sc.D., F.A.P.H.A.†

Third Vice-President, Metropolitan Life Insurance Company, New York, N. Y.

FOR the past two years, a study has been conducted in New York City schools, primarily for the purpose of finding out the reasons why extreme physical defects in school children remain uncorrected. The study has been directed by the Research Division of the American Child Health Association, in coöperation with the City Department of Health and the Department of Education, and with the guidance of an Advisory Committee representing the active participating, and certain other agencies. The committee was under the chairmanship of Dr. Philip Van Ingen, and the plan and research direction of the study was the work of Dr. Raymond Franzen (see full report). The inquiry was made possible by the financial support of the Metropolitan Life Insurance Company, in accord with the company's long established interest in and efforts toward the improvement of school health programs.

From the study there have been presented in the final report just published not only recommendations for changes in the New York City School Health Program, but also generalized principles of procedure that are deemed applicable

to other cities throughout the country. This discussion will center on those principles, merely drawing on the results as illustrative material.

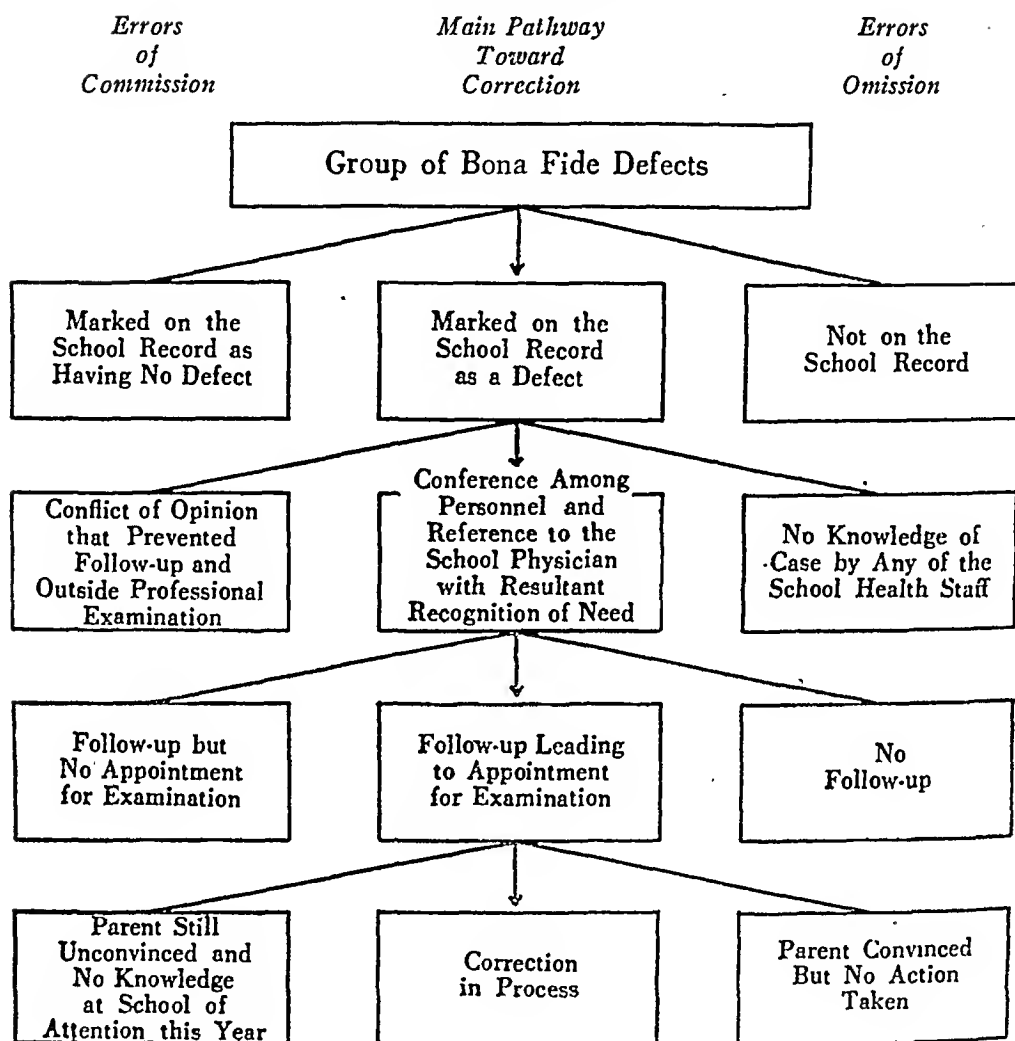

The plan of the study was somewhat unique. It concentrated on a limited phase of the school health program—the reasons for failure in securing corrections. This angle of the subject was emphasized in the belief that it would provide new points of view as to the effectiveness of the examination and follow-up efforts as a whole. The study first called for the independent and fresh identification of children with extremely severe physical defects which had not been corrected. This involved extensive preliminary work in the development of screening and verifying tests. The experience of the American Child Health Association in its School Health Study was drawn on heavily for this purpose. With the severe defect cases identified, the next step was an intensive investigation of these cases to determine the cause for the continued existence of the defect. The school records were inspected to see if the handicap had been routinely detected; the teacher was interviewed at length to ascertain what she had done to effect correction; the school nurse was questioned to find out what follow-up she had been carrying on; and, finally, a visit was made to the home in order to complete the information. Considerable preliminary experimental attention was expended in

† Prepared in collaboration with George T. Palmer, Dr.P.H., General Director of the Study for the American Child Health Association and now Secretary of the Department of Health of New York City; and Mayhew Derryberry, Ph.D., Associate Director of Research, American Child Health Association.

CHART I

METHOD OF CLASSIFICATION OF UNCORRECTED DEFECT CASES

developing the form of these inquiries. From an analysis of these exhaustive case histories, it was possible to determine what steps had been taken toward correcting the defect, if any, and wherein the failure had occurred.

As a means of summarizing the causes for failure, a schematic diagram was constructed (see Chart I), showing the usual steps that are taken in bringing about the correction of a defect. These steps, shown in the center of the chart, have been designated as the "Main Pathway Toward Correction." In addition, the chart shows the de-

viations or errors that may occur at each step in the procedure, thereby causing cases to be shunted out of the main pathway. The errors may be "Errors of Commission" (shown on the left), in that a wrong procedure has been followed, or they may be "Errors of Omission" (shown on the right), in that nothing has been done.

The first step on the pathway toward correction usually is an examination and the recording of the defect. The school may err in this step by failing to detect the severe condition, or it may fail to examine the child. Next, through a

pooling of information by the teacher, nurse, and physician, selected cases are placed on the nurse list for follow-up. In this step, there may be disagreement among the personnel concerning the need for follow-up or there may be a failure even to consider the case. Once the personnel are agreed on the need for follow-up, the remaining steps are usually follow-up, appointment for examination or treatment, and finally correction. The kinds of errors that occur at these stages are shown on the chart.

Four types of defects were studied in this manner: vision, teeth, nutritional status, and hearing. In addition, somewhat different types of investigation were made for tonsils, pediculosis, and awareness of health facts.

Perhaps the outstanding contribution of this study is the revelation of the major causes for lack of correction. These are not, as is so commonly believed, the lack of examinations or the failure of parents to respond. Primarily, they are the failure to identify the severe cases in the first place, and the failure to follow the cases through the successive steps to the desired outcome. Apparently, we have been too prone to blame parents for their indifference to information supplied to them. Actually, when the facts are closely examined, parents are less to blame than the school health program and the personnel involved in that program. In nearly nine-tenths of the cases with severe hearing defects, for instance, no notice had ever been transmitted to the parents. The same was true for two-thirds of the vision and nutrition cases, and for half of the severe dental cases.

The faults in the school health program may be traced to a number of causes, and these vary with the particular defect. In the case of hearing, the trouble lies almost wholly in the failure to detect the condition. It was either that no hearing test was ever made, or if made was never recorded, or

wrongly recorded as disclosing no handicap.

With dental defects, the situation is quite different. Children with bad teeth are usually known. They appear on the record. The loss comes in the second stage, in deciding which children to follow up. Here, great numbers with severe conditions are passed over with no further attention. The cause of this traces back to the method of marking defects in the first place. All the severe cases are noted, to be sure, but in addition to this, innumerable other cases of lesser severity are also noted on the records, and there is no distinction on the records as to the degree of severity. As a consequence, there is no basis for selection of the really severe cases, and children are chosen for follow-up on some other grounds than the severity of their dental defects. The number of children recorded with some dental defect is so great that the follow-up burden becomes overwhelming. The severe cases are lost in the very magnitude of the problem.

With vision and with nutrition, the losses are spread out over the different steps in the school health procedure. There is an appreciable loss at the outset in labelling cases normal when they actually have an extreme defect. Mistakes are made among the school health personnel in selecting cases for follow-up, and the follow-up itself is only too frequently superficial and ineffectual.

Lack of corrective facilities is a pronounced factor only in the case of teeth. But even here, only one-third of the parents are aware of the serious condition of their children's teeth. These parents have no excuse other than their inability or unwillingness to seek or find professional attention. The other two-thirds, as well as the parents of the children with vision, hearing, and nutrition defects, may properly plead ignorance. Little or no information has

been conveyed to them by school or health authorities concerning the cases under review in this inquiry. But let us not be misunderstood in these remarks. This study relates to severe uncorrected defects. When we say that the school health service has not conveyed information to parents in so many of these cases, there is no intent to imply that contact with the home has not been made for a great many other cases. Much successful corrective work has been instigated by the school health personnel. The study of these four conditions, it must be remembered, was focused on the severe cases that still remain uncorrected. It was limited to these cases and to an investigation of the failures in the attempt to identify the causes of the failure.

In the case of pediculosis, it was found, through a study of the activities of the personnel in a number of schools, that the reason for the failure to correct the defect, *i.e.*, delouse infested children, was the lack of a definite policy concerning the responsibilities of the nurse and teacher. The nurse considered that the teacher should see that the condition was cleaned up, and the teacher maintained that the nurse should do the necessary follow-up.

The investigation of the reason for failure to correct serious tonsillar defects could not be carried out in the same manner as the study of vision, dental, and nutrition defects. In the first place, there were no definite objective criteria of what constituted a serious tonsil defect. In the second place, a preliminary examination of 1,000 11-year-olds showed the rather astonishing fact that 61 per cent of the cases had already had a tonsillectomy. The study was then changed to focus on the methods of examination, recording, and follow-up that resulted in so many tonsillectomies.

Accordingly, the 389 children out of the original 1,000 who still retained

their tonsils were examined by a group of school examiners, and 45 per cent of them were recommended for tonsillectomy. The 215 cases not recommended by this first group of physicians were seen by another group of school examiners, and 46 per cent of these were recommended for tonsillectomy. The remaining 116 who had been marked as not needing attention by these two groups were seen by still a third group of school examiners, and 44 per cent of these were recommended for tonsillectomy. At the end of this experiment, there was left a residue of only 65 out of 1,000 who would not have had a tonsillectomy if all the recommendations of the physicians had been carried out. Furthermore, when a history was taken of the cases, practically no relation was found between the recommendations and a history of sore throats and colds.

The study of the follow-up revealed that nurses often followed up tonsil defects and neglected other serious conditions. In summary, the need in New York City with reference to tonsils is not more corrective work, as it was in the case of the other conditions, but rather more standardization and discrimination in the selection and follow-up that is carried on.

The experience in the study of these several defects gives rise to several recommendations for overcoming the difficulties that are revealed. The first is a proposal that the volume of the preliminary service—that is, the examination and the selection of defects—should be guided, if not determined, by the corrective services available. If the preliminary work is started wholly without regard to the corrective outlet, and the number of children started on the pathway to correction is so great as completely to overtax the outlet, then much of the preliminary effort is wasted. We say this advisedly. If there is no possibility of securing corrective service,

then there is no point in continuing to swell the number who need such service. We can either examine less or follow up only the really severe cases. In either case, it would seem to be far more sensible to save on the preliminary steps and devote effort and funds toward increasing the corrective service. As these services expand, then the preliminary examinations can be extended.

If we look at the matter frankly, I think we will agree that we have been too much concerned in getting children examined—examined quickly and frequently. We have been too little concerned with the character of the examination and with just how we were to make use of the facts gained from the examination.

The second proposal is that we should be more accurate, and, at the same time, more economical in identifying defects. Grave errors are now being made in picking out the cases most urgently in need of attention. Tonsils and nutrition as reported in this study are striking examples. There is no excuse for ignoring these facts. But improvement in accuracy does not necessarily mean increased expense. There are screening procedures that can be used first—simple tests in the hands of non-medical technicians, and histories as gathered from the daily observation of teachers. The time of the physician should not be used where others with less training can serve the purpose equally well. The physician—both the school doctor and the private family medical adviser, who can and should be utilized to a greater extent than at present—should be largely reserved for their professional, diagnostic, and therapeutic judgment, an attribute that others are unequipped to supply. Examples of these screening methods are discussed in the report.

Success in the correction of defects does not depend upon the doctor, the nurse, or the teacher alone. It is dis-

tinctly a coöperative job. There must be rapport between the different people concerned. This may sound trite. It is the old familiar coöperation which has been preached and preached and preached again. And yet, in spite of the best of intention and good will on the part of department heads, coöperation is often ignored in practice. There are glaring examples. There are doctors who spurn suggestions from a teacher. There are teachers who do not want to be bothered with any health matters. If families are going to be induced to do something about the facts disclosed in the school, then doctor, nurse, and teacher must work as a team. It is grossly ineffective to do otherwise.

This leads directly to another recommendation. The nurse must have information intelligible to the parent, backed by professional authority when she visits a home. It is not enough to tell parents about 2X tonsils or Number 4 Nutrition. She must equip herself with clinical facts, and the unfavorable history derived from school experience. Her source is the doctor and the teacher. There must be personal discussions. Records may be fewer, but fuller. If all the effort at follow-up is to mean something, then parents must be given substantial and convincing evidence. This is much more effective than the mysterious symbols used on the child's record card.

Further than this, there is the old question of records. Records must be alive. Cases should not be lost from official sight. Records should show the progress of any child on the pathway to correction. It should be possible to tell at a glance how many children and which children have reached each step along the pathway. This is a plea not for more records, but for records and filing methods better adapted to the needs.

The school medical program as now conducted is, in general, one of the least

efficient of our public health procedures. It has developed in a diversity of patterns, practically all of which represent different adaptations of the clinical or individual method to large school groups. These adaptations have usually resulted in just such inefficiencies as have been revealed in this study. Consequently, during the depression, this inefficient field of service has been the one that was most readily cut.

This study has not only pointed out the inefficiencies, but it has also sug-

gested new points of view applicable to large groups, and has indicated new lines of approach which should prove useful in the reconstruction of effective school medical programs. The committee that advised in connection with the work is unanimously convinced that those directly responsible for the inquiry have made a contribution of very great and far-reaching importance to the health and school organizations, and to the well-being of our urban school population generally.

Unemployment and the Physical Condition of Children in Germany

FOR the purpose of determining the effect of unemployment on the physical condition of children, studies have been made in several cities of Germany. In Kiel a study was made in 1933 of the records of physical examinations of 2,350 school entrants. The children were all 6 years old and were divided into 5 nearly equal groups, according to the family's economic condition. It was found that the average height and weight of children of unemployed persons on relief rolls and of partly employed persons were lower than those of children from better situated families and that the difference increased with the improvement in the economic situation.

A study made in Berlin in 1931 of 1,100 working class children varying in ages from 6 to 14, one-third of whom

were from unemployed families, showed that the average weight of the children of unemployed parents was $2\frac{2}{3}$ pounds less than that of children of employed parents, and the average height $\frac{3}{4}$ inch less. The study also revealed an inferiority in the general condition of the children of the unemployed, manifested by greater frequency of tuberculosis, nervous disorders, and difficulties of behavior.

In a study made in Vienna in 1932 of 800 children between 1 and 6 years old, half of whom came from unemployed families, it was found that 57.5 per cent of the children of the unemployed were below normal in weight, but only 34 per cent of the children of the employed.—*Archiv für soziale Hygiene und Demographie*, Berlin, vol. 8, No. 6, 1934.

Housing Problem in a Southern City*

With Special Reference to Its Influence on Residual Typhoid Fever and on Infant Mortality

L. M. GRAVES, M.D., AND ALFRED H. FLETCHER, F.A.P.H.A.

*Superintendent, City Health Department, and Sanitary Engineer,
City Health Department, Memphis, Tenn.*

ALL students of public health appreciate the fact that environmental hygiene plays an important part in the control of certain diseases. The term housing used in its broadest sense includes not only the house itself but the immediate surroundings, such as drainage, water supply, sewage disposal, the air breathed by the occupants, the presence or absence of sunlight, etc.

The relationship of housing to health has defied direct quantitative expression because of the many other factors indissolubly linked with the slums, such as poverty, ignorance, long and fatiguing hours of work, exposures to extreme weather conditions, malnutrition, inadequate medical and nursing care, etc.

It has long been recognized that the substitution of a safe for an unsafe water supply in a city is followed by a sharp drop in the typhoid case and death rates. It has also been observed, however, that the reduction is less marked in some cities than in others. This seems particularly true of southern cities as contrasted with those in other sections of the United States. Reasons for these higher residuals in southern cities seems

never to have been satisfactorily explained. Memphis in its early history obtained its water from Wolf River, a small stream which flows into the Mississippi at the site of the city. Later (1890) this source was supplemented by wells, but the system was still subject to contamination especially in flood season. In 1925 the use of river water was completely discontinued and a new system installed, using water from a series of deep wells. This last system has been recognized as a safe and satisfactory supply in every way. The typhoid death rate came down rapidly following these improvements in the water supply, as will be seen from the accompanying Figure I.

It will also be observed, however, that there remains a rather high residual.

FIGURE I

* Read before the Public Health Engineering Section of the American Public Health Association at the Sixty-third Annual Meeting in Pasadena, Calif., September 4, 1934.

An interesting point in this connection is the change in seasonal prevalence. A higher percentage of deaths occurred in the winter and spring in the periods from 1882 to 1899, and 1900 to 1919, before the installation of the present safe water supply than during the last period 1920-1932, but a higher percentage of deaths has shifted to the summer and fall months for the period 1920 to 1932 than during the early years (see Figure II).

FIGURE II

The relatively high typhoid rate in Memphis may be partially explained by the fact that the city is the only hospital center for an unusually large poorly sanitized rural area which contributes a large number of nonresident deaths; but the fact remains that the rate is still higher than would be expected when the nonresident element is excluded.

In an effort to explain this high residual, it was decided that a study of the possible relationship between the typhoid death rate and housing conditions in the city would be desirable. As it was felt that some of the same factors influencing the typhoid rate might also affect the infant mortality rate, which is also high for the city, it was decided to include infant mortality in the study. The opportunity to make such a study was offered by the Civil Works Administration Program. With the assistance of Rollo H. Britten, Chief Statistician

of the U. S. Public Health Service, a housing survey was carefully planned which was designed to yield information which it was hoped would shed light on the high typhoid residual and the high infant mortality rate, and could be used in other studies and in preparing an effective housing code for the city.

Thirty-five workers were employed for about 6 weeks. One block out of every 4 blocks in each ward was drawn by an architect or engineer, showing on a card the size, spacing, shape, and height of all buildings, and checked against the information on the survey cards which was secured on every living unit within these blocks.

Briefly the tabulated data will show:

1. The vacancy-occupancy conditions either by wards, by race, by condition of the house itself, and by state of sanitation and surroundings.
2. The physical condition of dwellings, by wards, or race and in other groupings, and including state of repair, construction of wood or other material, the roofing material, number of rooms, number without sunlight, number without windows and size of largest room.
3. The sanitation provided at each dwelling, grouped by wards or color. This included data on the source of water and how furnished to tenants. Whether have a bathtub and location of. How sewage disposed of, location of toilets, and safety of disposal method.
4. Pertinent facts concerning the tenants such as, persons per room in each living unit, the age grouping, number of pay boarders, families living in cellars, whether tenant owns or rents, weekly rental, and how long lived there.

A ward map of the city was prepared spotting those sections generally recognized by members of the Health Department as slum areas. They contain such conditions as those shown in the accompanying photographs, and were selected because of the obviously poor housing conditions. These pictures are inserted to enable students in other sections of the country to visualize the southern housing problem. The problem is not so much the lack of fresh air and sunlight, land or room overcrowd-

Poor Housing Conditions in Southern Slums

ing, as that until recent years houses have been built in the rear of lots and on alleys with outside communal toilets.*

Typhoid fever case rates, infant mortality rates, percentage without private toilets, persons per room, percentage of houses needing repair, and other factors, were computed for 9 population groupings:

- (A) and (B) Negroes in 2 groups of slum wards
- (C) For negroes in the suburban area or belt on the outskirts which has been recently annexed to the city.
- (D) For negroes in the remaining wards of the city.
- (A) to (D) inclusive. For negroes in the entire area studied.
- (A) and (B) For the white population for the 2 slum areas combined.
- (D) For the white population for the rest of the city exclusive of the recently annexed territory.
- (A) to (D) inclusive. For the white population for the city as a whole.
- (A) to (D) inclusive. For the combined white and colored rate for the city as a whole.

Table I shows these rates.

The typhoid fever case rates used in this paper are for the years 1929 to 1933 inclusive, which are the average number of resident cases per 100,000 population. The infant mortality rates are the average number of infant deaths per 1,000 live births for the years 1930 to 1932 inclusive.

It will be noted from this table that the highest typhoid case rates and the highest infant mortality rates are among negroes, and that the negro rates are highest in the slum areas. The highest rates for whites are also in the slum areas. A detailed study of the rates and factors involved in the suburban belt indicated that the rapidly changing conditions due to extensions of water and sewer mains and connections, together with nursing and sanitation service, make it necessary to exclude this area from our study.

Typhoid case rates for negroes in groups of wards within the slum area were studied in relation to the per-

* The word toilet as used throughout this paper does not refer to the privy but to toilets connected to the city sewer.

TABLE I

INCIDENCE OF TYPHOID FEVER CASES AND INFANT MORTALITY
IN 9 GROUPINGS OF THE POPULATION
COMPARED ACCORDING TO PER CENT WITHOUT PRIVATE TOILETS

Groups	Number of Wards	Area in Acres	Percentage Without Private Toilets	Population	Typhoid Fever Case Rate 1929-33	Infant Mortality 1930-32
"A" Colored	8	2,827	55.8	28,188	51.7	128
"B" Colored	6	1,554	92.2	13,446	38.7	118
"C" Colored	12	11,976	94.2	16,117	50.7	166
"D" Colored	24	12,822	60.0	38,799	35.0	111
"A + B" White	14	4,381	12.9	33,652	36.4	84
"D" White	24	12,822	2.1	102,766	22.8	53
Total Colored	50	29,179	69.2	96,550	41.0	128
Total White	50	29,179	8.5	156,528	27.0	64
Total	50	29,179	37.3	253,143	32.3	90.2

centage of families without private toilets which in Memphis means those families who use outdoor communal toilets. In a group of wards in which the percentage of families without

private toilets was 80 or above, the case rate was 64.2. In a group of wards where the percentage of families without private toilets was 60-79, the rate was 43.1. In a group of wards in which

Outdoor Communal Toilets

TABLE II
INCIDENCE OF TYPHOID FEVER CASES
AMONG COLORED IN SLUM AREAS
1929-33 INCLUSIVE
COMPARED IN THREE GROUPS ACCORDING
TO PER CENT
WITHOUT PRIVATE TOILETS

Group	No. Wards Falling in Group	Per-centage Without Private Toilets	Popu-lation	Ty-phoid Cases	Aver-age Annual Case Rate
A	4	80 & over	7,793	25	64.2
B	6	60-79	20,786	45	43.1
C	4	60 & less	13,055	19	29.1

the percentage of families without private toilets was below 60, the rate was 29.1 (see Table II).

A study of the negro infant mortality rates, however, did not seem to show a relation to the percentage of families living without private toilets as in the case of typhoid fever.

In order to make further comparisons of housing conditions to typhoid fever and infant mortality, a housing index was calculated for each ward by using the following three factors:

1. Persons per room
2. Percentage of dwellings not in good repair
3. Percentage of living units with outdoor toilets

The rank for each ward for each of these factors was obtained, placing them in order with the poorest ward at the top as No. 1, the second poorest ward as No. 2, etc. The average of the numbers representing the numerical rank of the ward for the 3 factors was taken as the housing index for that ward. This index was calculated for colored and white races, and in each case those

TABLE III
COLORED INFANT MORTALITY AND
TYPHOID FEVER CASE RATES
GROUPED BY WARDS
ACCORDING TO VARYING HOUSING INDICES

Group Index	Number of Wards	Typhoid Case Rate	Infant Mortality
0-4	4	59.4	177
5-9	4	39.4	118
10-14	8	36.7	117
15-19	6	38.3	113
20+	6	39.5	91

wards having the lowest housing index as a group, had the highest typhoid rate and also the highest infant mortality rate. The next high group had a lower rate and the highest group had the lowest rates. Although in the previous table the infant mortality rates did not show a relation to outdoor toilets, it did to groups of wards having varying housing indices as shown in Table III.

TABLE IV
WHITE TYPHOID FEVER AND INFANT
MORTALITY RATES
GROUPED BY WARDS
ACCORDING TO VARYING HOUSING INDICES

Group Index	Number of Wards	Typhoid Fever	Infant Mortality
0-12	12	47.8	78.8
13-24	12	17.3	69.2
25-37	13	22.7	48.6

TABLE V
CORRELATION OF WHITE TYPHOID RATES
ACCORDING TO PER CENT COLORED
WITHOUT PRIVATE TOILET

No. of Wards	Colored Rates	White Rates
9	50 or more	40.9
10	less than 50	20.0

In the case of whites a relation was also indicated between wards with low housing indices and high typhoid fever and infant mortality rates as shown by Table IV.

It is interesting to note that in the group of wards where the colored typhoid fever rate was 50 or more per 100,000 population, the white rate for these same wards was 40.9. In the remaining wards with rates of less than 50 per 100,000 population for the colored, the white rate was 20.0. This

correlation exists even though the percentage of outdoor toilets among the whites is negligible in all wards (see Table V).

OBSERVATIONS AND CONCLUSIONS

1. In this study both typhoid case rates and infant mortality rates were found to be highest in those wards which are obviously slum areas.

2. Typhoid fever rates for the colored in slum areas showed a relation to wards grouped according to percentage of living units without private toilets.

3. Infant mortality rates for the colored in slum areas did not show a relation to wards grouped according to percentage of living units without private toilets.

4. Wards were grouped for purposes of comparison according to a slum index.

5. Typhoid fever case rates and infant mortality for both the white and colored races showed a relation to wards when grouped according to their slum index.

6. Typhoid fever rates for the whites showed a relation to wards when grouped according to typhoid fever rates for the colored race or when grouped according to percentage of colored living units without private toilets.

DISCUSSION

CHARLES GILMAN HYDE, F.A.P.H.A.

Professor of Sanitary Engineering, University of California, Berkeley, Calif.

THE authors have presented a paper of great value and interest and are deserving of the highest commendation. A vast amount of statistical work has been involved in its preparation. The information contained therein is of the sort which is fundamental to a better understanding of the complex and interwoven factors concerned with the matter of housing as related to health in general and, more specifically in this case, with respect to residual typhoid fever and infant mortality.

When once the water and milk supplies have been removed as sources of infection, the problem of typhoid fever incidence becomes one of the restricted local environment. The main factors

are contact and flies, and possibly certain contaminated foods. To the extent that housing reflects these factors or conditions, to that degree residual typhoid fever may be related thereto.

The relationship between the public water supply and the typhoid fever death rate through a considerable period of years has been well and explicitly shown by the authors. With the decreasing use of Wolf River water, a polluted source of supply, and with improved sanitation in other respects, the typhoid fever death rate was notably reduced until at length, in 1925, the public water supply was no longer involved. The death rate has been reduced from about 95 in the 10 year

period from 1880 to 1889, as shown by the authors, to about 23.5*¹ in the years 1924-1926 inclusive; and to a residual in 1929 of only 5.3.¹ It is safe to say that it is only a matter of time, and perhaps a relatively short period, when the typhoid fever death rate in Memphis will have reached a very low and, in a practical sense, an almost insignificant value.

The City of Memphis is fortunate in having an abundant supply of ground water (well water) of highest quality in every respect. There are only 3 other cities in the United States at the present time, having populations in excess of 100,000 which derive their entire supply of water from the ground: Dayton, Ohio (population 200,000), Lowell, Mass. (population 100,000), and Spokane, Wash. (population 116,000).

It is to be expected that, under the existing circumstances, the elimination of the public water supply as a factor in the typhoid death rate would de-

crease the percentage of cases occurring in summer and fall. With the lowered incidence of typhoid, in general, the number of carriers is proportionately reduced, presumably, and the volume of infectious material likewise reduced. Thus the fly infection danger, although always significant so long as there are exposed typhoid dejecta, becomes less menacing and important. The saying that "Nothing succeeds like success" applies well to the warfare against infectious diseases such as typhoid. Once the absolute incidence is lowered, all possible sources of local environmental infections are also reduced.

In the time available to the speaker since the receipt of this paper it has been impossible to review in detail the climatic conditions of temperature, rainfall, and humidity which might have a more or less controlling effect upon fly breeding. However, the monthly rainfall, temperature, and humidity statistics for Memphis for the year 1930 were compiled.² These are presented in Table I. It is hoped that the conditions for 1930 were sufficiently typical

* Actually typhoid and paratyphoid, with rates approximately as follows: 1924, 31.1; 1925, 24.5; 1926, 15.6.

TABLE I
RAINFALL, TEMPERATURE, AND HUMIDITY AT MEMPHIS

Minimum	0.14	63	40	40	36.2	43.2	29.2

to warrant the making of certain deductions therefrom.

Hutchinson³ has shown that flies are fairly active at 55° F. and very active at 65°. A mean daily temperature in the vicinity of 60° may perhaps be assumed to represent the critical temperature below which fly breeding will not be very important and above which it may become serious. If this is true the fly breeding season in Memphis would perhaps begin in April and continue to or through October. Typhoid due to fly infection might therefore be expected to occur from May to November, reaching a peak in July and August. In 1930 the months of June, July, and August were relatively dry, both in terms of rainfall and humidity. This condition would not perhaps greatly affect fly breeding in covered spaces, but it would reduce that which might otherwise occur in scattered manure and feces out of doors.

The unscreened houses and communal toilets shown in the photographs suggest that aggravated conditions of fly

infestation and infection may obtain. Such infections would, of course, normally be reflected in the typhoid incidence and in infant mortality as well, especially in that portion due to diarrhea and enteritis. The communal toilet is almost bound to be unspeakably filthy, occasionally if not continuously. It may cause the use of the ground and of all sorts of protected spots for both urinal and fecal discharges. To what extent this practice prevails is not revealed by the authors.

The authors' findings indicate that the typhoid incidence is closely related to the extent of use of the outdoor communal toilets. The travel habits of the fly are such that it may be expected that typhoid would occur among populations provided with private toilets if their abodes are in the general vicinity of filthy outdoor toilets.

With reference to infant mortality Whipple⁴ has stated:

No part of vital statistics is attracting more attention nowadays than the subject of infant mortality. It is, indeed, a serious problem

TABLE II
STUDY OF CONDITIONS IN JOHNSTOWN, PA.
1915

Dirty dry homes versus clean dry homes	162/105	154%	Midwife's attendance at birth versus physician's attendance at birth	180/100	180%
Dirty damp homes versus clean damp homes	204/127	161%	Foreign illiterate mother versus foreign literate mother	214/148	145%
Dirty damp homes versus clean dry homes	204/105	194%	Artificial feeding only, average of 2nd and 3rd months of life, versus breast feeding only during that period	227/63	360%
Yard privies versus water closets	159/108	147%	Very inadequate income, foreign parents, versus adequate income, foreign parents	251/108	232%
Outside, only, versus inside water supply	198/118	168%	Very inadequate income, native parents, versus ample income, native parents	146/78	187%
Baby sleeping with others versus baby sleeping in separate bed	109/56	195%	Very inadequate income, foreign parents, versus ample income, native parents	251/78	322%
Baby sleeping in room with more than 5 others versus baby sleeping in room alone or with 1 other only	123/67	184%			
Baby's room poorly ventilated versus baby's room well ventilated	169/28	604%			

and worthy of most careful study. It is a complex problem and one difficult to understand. It is a problem which goes beyond itself. Newsholme says that "infant mortality is the most sensitive index of social welfare and of sanitary improvements which we possess." Another says that "infant mortality is to the health officer what the clinical thermometer is to the physician." People who will not take care of their offspring will not take care of themselves.

The authors have very appropriately pointed out that infant mortality is inextricably associated with a great variety of social and economic factors as well as those represented by the physical environmental conditions. The relationship to a considerable number of such factors is shown in an illuminating fashion by an analysis of the results secured by an intensive study of infant mortality at Johnstown, Pa., in 1915, by the Childrens Bureau, U. S. Department of Labor.⁵ Some of these factors

and their effects, expressed in terms of the greater infant mortality under adverse conditions than under fair to excellent conditions, may be stated as shown in Table II.

Some of the conditions recited there undoubtedly have a direct bearing upon infant health. It is obvious, however, that others are in themselves not directly involved but they do reflect generally low or adverse conditions which are immediately associated with a high infant mortality rate.

Effective health control in cities with large percentages of colored population unquestionably represents a very much more difficult problem than that encountered elsewhere. In spite of this handicap many such cities have made remarkable progress. This is the case with Memphis. The writer inclines to the belief that the conditions of health today in southern cities with well or-

TABLE III

ESTIMATED TOTAL POPULATIONS AND DEATH RATES TOTAL (ALL CAUSES), INFANT AND TYPHOID FEVER, FOR CERTAIN NORTHERN AND SOUTHERN CITIES IN THE UNITED STATES, YEAR 1929¹

† per 100,000

ganized health departments are simply those of a comparatively few years ago in northern cities which had no such handicap. This lag will assuredly be gradually overcome except in so far as basic inherited and inherent population tendencies and traits control ultimate progress. As a matter of interest in this connection the speaker has selected, somewhat at random, 7 northern cities with no very considerable colored populations, and 7 typically southern cities, including Memphis, all places in both groups having as nearly as possible the same population as Memphis. For these 14 places for the year 1929 the crude total death rates (all causes), typhoid fever death rates, and the infant death rates have been computed. The figures are presented in Table III. It will be observed that the estimated average population of the 7 northern cities is

283,000 and that of the 7 southern cities is 289,000.

While the average typhoid fever death rates in the selected southern cities is several times those in the northern group of cities, the former is not high, in absolute terms, and is so small in comparison with those of many other diseases as to constitute an almost negligible proportion of the total death rate. It should be noted that in all of the cities included in the table the public water supply is of excellent quality and is not a factor in the typhoid fever death rates.

Imagination in Public Health

" . . . We have always been impressed from our earliest student days with the presence of the great killing diseases. Much greater is the conception that these diseases are primarily the disabling diseases of succeeding generations. Whatever we die of in a way matters less than how we live, and we should in our visualisation of preventive medicine be far more deeply concerned with the causes that underlie the disabilities of the active periods of life than with the specific and direct agencies of death. If we so concern ourselves in our considered thoughts we shall, in fact, eventually attain a much higher level of accomplishment than is otherwise possible to us. What is the vision that we therefore have? Briefly, it is that the minor disablements, the

chronic incapacitation of life—such as susceptibility to respiratory catarrhs, chronic dyspepsia, hepatic inefficiencies, disorganisation of the functions of endocrine glands, practically all of the ailments which make for so much of life's discomforts and restraints from full activity—are the manifestations in succeeding generations of injured germ plasm.

Expressed in another way, I would put it to you that the great mass of minor human ailments is the result in succeeding generations of the damage that has been done to parents or grandparents by the presence of one or more of the great disabling diseases. . . ."
—Dr. R. Veitch Clark, *Imagination in Public Health*, *Public Health*, Nov., 1934, p. 61.

The Public Health Officer and the Control of Syphilis*

JOSEPH EARLE MOORE, M.D.

Baltimore, Md.

I HAVE never accepted an offer to speak before a gathering of physicians with more diffidence than on this occasion. For me, a clinician, to address an audience of public health officials on the subject of the public health aspects of syphilis control is indeed like carrying coals to Newcastle; and this is especially true since your own Commissioner of Health, Dr. Parran, is without question the foremost authority in the country on this topic. To cover the whole field adequately, it would only be necessary for me to repeat verbatim his De Lamar lecture¹ of 3 years ago.

Nevertheless, the clinician engaged in syphilology cannot fail to have rubbed elbows with the public health officer, to have formed some personal opinions as to the adequacy of our present mode of approach to the problem, and to have acquired ideas as to the best method of attack in the immediate future. This is my excuse for addressing you. I hope that you will regard my ignorance of matters administrative and political with leniency and make allowances for the fact that I am invading unfamiliar ground. I hope for pardon, too, if I utilize my own city, Baltimore, as a background for some of my statements and opinions. After all, what is applicable in a large city of one state is—

or should be—equally applicable to other large cities.

I have emerged from 15 years of experience in clinical syphilology with several firm convictions. These are: (1) that syphilis is easily the most prevalent of the major communicable diseases; (2) that, directly and indirectly, it costs the taxpayer more than any other infectious disease; (3) that there are already available the weapons with which it might be, if not entirely stamped out, at least reduced from a major to a minor problem within a generation; (4) that though these weapons have been available for a decade or more, we are progressing not forward, but backward—syphilis in this country is actually increasing, not decreasing; (5) that the blame for this paradoxical situation may be placed, at least in part, on the shoulders of the public health officer. This last is, I realize, a bold statement, and may, indeed, like many of the arguments of my fellow townsman, H. L. Mencken, be an over-statement, purposely made to startle an audience. I think, however, that it can be justified. Let me amplify my several points.

In Baltimore, during the 5 year period, 1929–1933, there were more cases of syphilis *reported* to the City Health Department than of any other communicable disease.² Its only close contenders are chicken pox, measles, and influenza.² More than 18,000 cases of

* Address before the annual convention of Health Officers and Public Health Nurses, Saratoga Springs, N. Y., June 26, 1934.

syphilis have been reported during these 5 years. Startling as these figures are, it is estimated that they represent less than half of the new cases discovered. Three reasons lead to the certain knowledge that the actual number is far larger than the reported number: (1) that reporting is required by name and address, and the regulation is thus obeyed only by hospitals and clinics, but by few or no private practitioners; (2) that the Health Department has heretofore required only the reporting of fresh infections, not of patients with late syphilis, even if diagnosed for the first time; (3) the study of venereal disease prevalence in Baltimore carried out by the U. S. Public Health Service and the American Social Hygiene Society,³ which estimates (1930) that the annual incidence rate of early and late syphilis is 8,460 cases, more than double the 3,276 actually reported to the Health Department in that year. Were all freshly diagnosed cases reported, whether early or late, I am convinced that the number of cases in Baltimore during this 5 year period would nearly treble that of its nearest competitor, varicella. More than that, each of the years, 1929-1933, has seen a progressive increase in the number of cases of syphilis reported: in 1933, 4,500 as compared with 3,100 in 1929. Worse still, the deaths from syphilis—counting only those reported to the Health Department as actually due to syphilis—exceed the deaths from any other communicable disease except the two leaders, pneumonia and tuberculosis. This statement does not include the deaths from syphilis masquerading under more polite but less definite names. Could these be identified, I believe that syphilis, instead of ranking third as a cause of death, would actually have topped all other communicable diseases. Considering the stress that is laid among public health officials themselves and in the lay press on the reduction of the

comparatively trivial mortality from, let us say, diphtheria, this is a sorry record indeed.

Now as to my second point, the costs of syphilis to the community. This is almost impossible to determine with accuracy, because the ramifications of the disease are so wide. It spreads from the free clinic to the hospital wards, from the private practitioner to the state insane asylum, from the obstetrical clinic to the deaf, dumb, and blind asylums. The nearest approach to accuracy has been provided by Loeffler,⁴ in his 1932 study of the costs of venereal disease to St. Louis. Here, gonorrhea and syphilis are not separated, though from his data it may be assumed, I think, that syphilis is responsible for the great majority of the financial burden. Nor does he attempt an estimate of the vast economic loss to industry and society through the incapacity and death of afflicted persons. The actual cost of venereal disease—largely syphilis—to the tax payers of St. Louis is estimated at \$600,000-\$1,000,000 annually; and in addition, another million and a half is spent by patients for physicians' fees and for private hospital care, or for patients by such welfare and charitable agencies as the private hospitals themselves, the Community Fund, etc. Of the million dollars expended by the tax payers, however, only a drop in the bucket—about \$60,000—is spent where it would do the most good, *i.e.*, in the treatment of early syphilis. The rest goes to the upkeep of broken-down cardiacs, the blind, the insane—in short, patients who not only are no longer a public menace, being no longer infectious, but who are also for the most part relatively hopeless therapeutic problems.

In Baltimore, a million dollars represents 10 cents in the tax rate—10 cents on each \$100 worth of taxable property. No estimates of the cost of syphilis in Baltimore are available, but

it is a city of almost exactly the same size as St. Louis, with a larger proportion of negroes—which in the depression is synonymous with a larger proportion both of indigents and of syphilitics—and hence with a bill of approximately the same or greater size. And in Baltimore, as in St. Louis, most of this money is spent, not where it might help to minimize the problem of syphilis, *i.e.*, on the adequate treatment of recent infections, or on the prevention of late progression or relapse by the treatment of latent syphilis, but on the patient whose late lesions, often crippling, have already developed.

My third and fourth points need little elaboration. Everyone knows that with the arsphenamines and the heavy metals, the infectiousness of syphilis may be controlled; better still, the disease may be "cured." Our difficulty in this respect has not been that the weapons were lacking. Rather, it lies in two other facts: (1) the widespread ignorance of physicians as to how to use the available methods of attack, an ignorance which extends, unfortunately, even among the medical personnel of some clinics run by Departments of Health; and (2) our inability to persuade patients to continue treatment to the necessary limits. I shall offer presently my own opinion as to practical methods by which public health officials may meet, at least in part, these two difficulties. As to the effects of our failure to utilize available methods, I need not weary you with detailed statistics. It is necessary only to point the contrast between the rising trend of syphilis in Baltimore and northern New York State, for example, with the equally rapidly falling trend in England and in Denmark.

As to my fifth belief, that some of the blame for this situation rests on the shoulders of the public health officials, I must attempt to justify myself. I cannot think that public health experts

fail to recognize the magnitude of the syphilis problem. The facts are everywhere protruding like a sore thumb. The simile is reasonably apt, since, like a sore thumb, syphilis is something to be hidden. With the average physician, practitioner or public health official, as with the average layman, syphilis is inextricably tied up with vice, prostitution, and penitentiaries. It is a disease which always attacks somebody else's family, never one's own. It is not to be mentioned in public; in fact, and except for a brief period of publicity during the war, it cannot be mentioned in the press of Baltimore, except by the nauseous euphemism of "social disease"; and Parran's achievement in having its name spread across the front pages of New York papers is almost unique as a public health and a journalistic achievement. There is a conspiracy of silence regarding the venereal diseases in which I believe that public health officials not only share, but for which in large part they are responsible. Their responsibility lies in the fact that, far more than other physicians, they are involved in intimate relationship with every other member of the medical profession and with the lay public. So far as communicable diseases are concerned, they are, or should be, the mouthpieces of medicine.

The conspiracy of silence involves their relationships with the medical profession itself as well as with the laity. It begins, unfortunately enough, in schools of hygiene and public health. The catalogue and announcements for 1933-1934 of the School of Hygiene and Public Health of the university with which I am connected lists, in the course of the 2 year program leading to the degree of Doctor of Public Health, only a small fraction of one short course on the subject of venereal disease control, in the midst of a welter of courses on parasitology, bacteriology, vital statistics, sanitation, etc., and no

hours at all are devoted to practical work in the venereal disease clinics, familiarity with which is essential if the Doctor of Public Health is to know one of the greatest of his future problems.

It extends to the relationships of the health department with practitioners of medicine. Many health officials feel that their duty as to syphilis is complete when they have provided a free Wassermann service and a free clinic for the treatment of the poorest class of infectious patients. Relatively much less stress is laid on syphilis than on the 10 times less prevalent diphtheria, or even on the nearly extinct dodo, typhoid fever. There is no organized effort to develop a sane method of reporting new cases, a method with which practitioners will cooperate because the secrecy which their patients demand is respected, not violated. Syphilis is not classified as a communicable disease, but as a problem apart. It is of interest that even in the weekly *Public Health Reports* of the U. S. Public Health Service, which provides the weekly incidence of a number of communicable diseases in the registration area, syphilis is not listed among them though it is the most important of them all.

Syphilis is at least mentionable between physicians. It is when the health official meets the layman that the conspiracy of silence is still more evident. I lay no particular stress on the fact that in contacts with the general lay public, syphilis is rarely if ever discussed. I am one of those who believe that so far as the medical profession's relationship to venereal disease control is concerned, it is hopeless to place much reliance on the sex education of children in schools, or of adults through pamphlets, radio talks, or magazine articles, or, for that matter, on any part of the complex program advocated by the social hygienists except that which deals with medical control. That part of the population which needs instruc-

tion most is the very part incapable of assimilating it. Those who can understand are, for the most part, already able to protect themselves, or through prudery refuse to read or listen. There is, however, a selected group of the laity with whom the public health officer must talk, namely the political officials in charge of government. It is necessary, of course, to sell one's budget to an audience of laymen—city councilmen, state legislators, congressmen. It is easier to lay stress on the dramatically swift consequences of the acute exanthemata than on the dreary chronicity of ultimate breakdown from syphilis. It is easier to arouse public interest and support for funds for free antitoxin for diphtheria control, for milk for malnourished babies, for wholesale tonsillectomies on inspected school children, even for the control of hog cholera, than it is for the victims of syphilis—a disease which is, to use the old Army phrase, the result of one's own misconduct. Unfortunately, this line of least resistance is usually adopted.

In one respect, of course, and whether or not his job is due to political favor, the public health officer often feels that his position is similar to that of other public servants—he cannot proceed faster than public opinion will permit. At present, he believes that public opinion is unwilling to face the facts about syphilis. Therefore, let us wait until it is better prepared. But the public health officer is dealing with a highly technical field in which he must lead, not follow, public opinion; and in no disease does that opinion require intelligent professional leadership so much as in syphilis. Again, one must admit the fact that in any public office, including that of public health, things are accomplished by a system of political give and take. Making all allowances for these two factors, however, it ought to be possible for the public health

officer to use three arguments in dealing with his political confrères: (1) that syphilis is the most prevalent and, therefore, the most deadly of the major communicable diseases; (2) that the disease is not always the result of one's own misconduct, indeed, that innocently acquired marital infections and congenital syphilis make up nearly half of the total, and that a baby dead of congenital syphilis is fully as pathetic as one dead from diphtheria; (3) that even if every infection with syphilis were acquired by means of commercialized vice, it would be an actual saving in money to the community to provide the means for all to receive early adequate treatment, with the aim of reducing not only infectiousness and the spread of the disease to others, but also the late sequelae, and hence the amount of money which must otherwise be spent on the treatment or charitable care of patients with aortic aneurysm, tabes dorsalis, or paresis. The politician is, I think, definitely interested in saving money; the depression has taught him that. Even if the politician is deaf to economic arguments, the tax payer is not. His interest is a keen and urgent one. It is probably true that the expenditure of \$10,000 yearly for the treatment of early and latent syphilis will save the community an ultimate \$100,000 per year. Even though this be a relative rather than an absolute saving, in the sense that hospital bed space and charitable care now expended on syphilis are freed for other purposes rather than completely eliminated, the community gain is worth while. Presented in this fashion, and backed by the easily obtainable opinion and support of medical and lay leaders, I believe that even the deafest politician may be persuaded to listen. He might even be brought to the point of transferring to syphilis control some of the money now spent on more purely political or less productive purposes.

If the health official's job depends on partisan politics, of course his situation is well nigh hopeless. If, however, his tenure of office depends on the efficient performance of his duty, he should certainly have courage enough to appraise the syphilis problem in his community, to determine how much money is necessary to deal with it properly, and to attempt to get the money. It is his job to point out that syphilis control promises more of immediate and ultimate community benefit than some other more purely cultural or mayhap political item.

I realize fully how presumptuous it may be for one who is neither public health officer nor political official in charge of government to attempt to appraise the relative value to the community of various items in the municipal, state, or national budget. In Baltimore, however, out of a total expenditure of 43 million dollars for 1934, the appropriation for the Health Department is only \$686,000 (1.6 per cent), and within that appropriation, the allocation of funds to venereal disease control is only \$39,000. This relatively insignificant sum is inadequate to permit the treatment of all applicants at the overcrowded city clinics, so that, in order to keep within its budget, the Health Department has been forced to accept only those cases which are actually or potentially infectious, and therefore a menace to the public health. Only the following categories of patients are now acceptable: those with primary or secondary syphilis, those with early latency (*i.e.*, infections of less than 3 years duration), or, if no history of infection is obtainable, women under the age of 40 (because still within the childbearing period), and men under the age of 25 (because presumably infection has been relatively recent).

The result of this policy (which, from the point of view of the Health Department and its budgetary restric-

tions, I must defend, since I assisted in framing it) is that the treatment of practically all patients in Baltimore with late—and especially latent—syphilis is thrust upon the shoulders of 6 clinics run by one state hospital and 5 privately endowed hospitals. Only 2 of these 6 clinics are large. Their facilities are utterly unequal to the burden; patient after patient with late or latent syphilis must be turned away with some such statement as: "You have syphilis and should be treated for it. We are unable to accommodate you here; the city makes no provision for your care; your only chance to be treated is either to pay a private practitioner or (since this is usually impossible) to tell the mayor or your city councilman of your difficulty and to request relief." It was estimated that this situation could be corrected, and treatment facilities provided which would ultimately have saved the city or state the cost of many hospital bed days through the prevention of progression or relapse in treated patients, by the additional expenditure through the Health Department of \$10,000 yearly; yet this sum of money could not be obtained!

Let us assume that the public health officer in drawing up his budget has assigned to syphilis the major importance it deserves, that he is willing to emphasize this item in his dealings with the budgetary authorities, and that he is successful in selling the idea of its essential nature—how can the funds thus secured be best employed to reduce the incidence of the disease? No amount of thought would enable me to put the remedy more succinctly than it has been put by Parran:¹

In principle, the whole problem of the control of the venereal diseases comprises just two elements; first, every infected person must take treatment promptly after infection, and second, facilities for diagnosis and treatment must be made available and must be utilized. These two administrative factors are self-explanatory.

The problem may be stated from a different viewpoint in terms of basic principles:

Legal aspects of the public health program should include: notification of cases, particularly lapsed cases; notification of sources of infection; authority to examine contacts; quarantine of irresponsible patients after other efforts have failed.

Medical services to insure early diagnosis and complete treatment should comprise laboratory diagnostic facilities, including dark-field examinations, adequate clinical services on a full payment, partial payment, and free basis; free distribution of drugs as necessary, to physicians as well as to clinics; payment of physicians in rural areas and small villages for treatment of those unable to pay; and early preventive treatment after exposure.

Epidemiologic measures should include intensive inquiry in every early case both in clinic and private patients, to determine the source of infection; examination of contacts in families and elsewhere; and concentration of effort where necessary on early infectious cases.

Medical social service and nursing assistance should be available to physicians as well as to clinics for the purpose of assisting family adjustments, of making visits to the home, of returning lapsed cases for treatment, and of persuading contacts in homes and elsewhere to be examined and if infected to seek treatment.

Education should include training of the necessary public health personnel; physicians, nurses and social workers; better training of private physicians by undergraduate and post-graduate education and part-time service in clinics; education of the public by every available method, including education of special groups in prophylaxis; and specific training of the patient.

On certain of these items, I as a clinician lay particular stress. As to notification of cases, it seems to me highly desirable that a uniform system of reporting the venereal diseases be adopted throughout the registration area of the United States; that the persuasive prestige of the U. S. Public Health Service be brought to bear upon state and municipal health departments in an effort to secure such uniformity; that this system safeguard the identity of the patient by avoidance of the use of name and address; and that its observance be repeatedly and constantly urged

upon practitioners through frequent bulletins issued by health departments. Could this be accomplished—and surely it would cost relatively little—we should at least have a clearer idea of what our problem is, and what impression we are making upon it.

Such legal measures as are involved in the prevention of delinquency and the suppression of commercialized vice are not properly part of the public health officer's duty nor chargeable against his budget. Nevertheless, his intelligent interest and coöperation with the proper agencies of law enforcement may be of far reaching influence, with no expenditure other than of his time.

The provision of adequate medical services is the crux of the situation. I have already said that although we have had available for a decade or more the means of dealing with the syphilis problem, they are not being applied, and that the fault lies squarely on the shoulders of the medical profession. There is, I think, no use in blinking the fact that, by and large, syphilis is badly managed by the average practitioner, and that, by and large, the service provided in the average venereal disease clinics, whether run under public health or private auspices, is not much better. In private practice, the faults are of both omission and commission. Even when outspoken lesions are present, syphilis is often erroneously diagnosed because of failure to do a Wassermann test. There is little or no concerted effort to detect the latent syphilitic (who is at least potentially a carrier) by means of routine Wassermans. Why this should be when free Wassermann service is so amply provided by health departments generally is a mystery. When syphilis is recognized, it is usually poorly treated; there is little or no effort to determine the source of infection or to examine contacts. Clinic service is better than this in some respects, but fully as poor in others.

As I have already said, the reasons seem to me to be two: actual lack of knowledge on the part of the medical profession on the one hand; and whether or not this is present, inability or lack of desire on the part of patients to carry through with the necessary examinations and treatment because of the vastly important economic factor.

How can we improve the standard of knowledge of the medical profession, and if it can be improved, in what way can public health officials be of aid in this connection? Education begins, of course, in medical schools. A recent survey by the American Social Hygiene Association of the facilities available for teaching syphilis to medical students in the seventy-some schools in the country⁵ disclosed that in many of them these facilities, or the amount of time devoted to them, are woefully inadequate. Perhaps it might not be amiss if the public health authorities, beginning with the U. S. Public Health Service and extending downward to state, county, and municipal public health services, were to outline to the deans of the several schools the magnitude of the problem in the country at large and in their several communities, and to urge that the facilities for teaching syphilis to students be expanded or more largely utilized. Assuming, however, that with public health and other pressure the instruction of students could be brought up to a uniform standard of excellence, it would require a generation for this improvement to make itself felt in practice. We want quicker action than this.

Quicker action may be obtained, of course, only if the standards of physicians actually in practice can be improved, and if patients with syphilis can be brought into the hands of the physicians. Let us consider these points. The overwhelming majority of practitioners are beyond the reach of formal medical education. There are,

so far as I can see, only two ways in which knowledge can be imparted to them. The first, through medical journals and medical meetings, has been tried and found wanting. The syphilologists of the country have done and are doing their part; indeed, some of us have written and talked so much as to have been diagnosed as afflicted with *diarrhea ex oribus*. Nevertheless, efforts along these lines should be both continued and expanded.

The second is a method which has so far hardly been tried, but in which public health officials themselves should figure largely. The health officer is *par excellence* the physician who is in constant contact with every other physician in his community. He bombards us monthly, weekly—nay, sometimes daily—with bulletins as to infantile diarrhea, measles, undulant fever, etc.; he has been responsible for inaugurating the wholesale immunization of children against diphtheria, scarlet fever, and even tuberculosis. In Baltimore, in the monthly bulletins sent out by the Health Department to every physician, syphilis (or the venereal diseases) were allotted 9 pages of space out of a total of 234 pages during the past 2½ years, as contrasted with 11½ pages for the vastly less prevalent and less serious but socially more appealing diphtheria.

Let the public health officer now recognize that syphilis is his major infectious disease problem. Let him add to his bombardment a steady stream of literature urging the more widespread use of free Wassermann service, of free arsphenamine when it is available. Let him teach us, with constant repetition of short summaries, such accepted procedures of treatment as those advocated by the Coöperative Clinical Group, how to use drugs in treatment, the desirability of epidemiological study of each case, the reasons for spinal fluid examinations, for the examination and treatment of pregnant women. Let him

realize that constant emphasis and repetition will accomplish educational results unattainable by a single address to a medical society, and that a program of this sort, if undertaken, should be kept up for years. Finally, let him clean his own house by making certain that his own syphilis clinics meet a minimum required standard of excellence, that the physicians employed in them are employed because they know something about syphilis, not because they need the job and happen to be friends of State Senator Doe. Let him offer, if local laws allow, his own clinics as instruction centers to practitioners, who may, by a few weeks' volunteer work, learn to handle the disease better (and incidentally more profitably) in their own patients.

Next, to face the problem of how to get the patient with syphilis into the hands of the presumably instructed physician or clinic. This involves, as I see it, two elements. It is essential to eliminate the quack advertising specialist and drug store treatment. Where laws permitting such action exist, they should be utilized; where they do not exist, their legislative passage should be urged by every possible means. Suppression of quackery is capable of accomplishment by legal means in an intelligent civilization: *vide* Denmark, which has had no quacks or cultists for more than 100 years; or even by extra-legal means, as one dynamic health officer in a northern New York city discovered. More important than this, however, is to find some way of bringing together the physician and the infected person who does not know he is infected or who thinks that he has been cured as a result of previous inadequate treatment. Here there are several avenues of approach. One is the urging of the routine Wassermann test upon hospitals which do not now employ it, and upon physicians engaged in industrial medicine. The facilities of

health department laboratories should, if necessary, be offered for this service. Better still is an advertising campaign, carried on in toilets, rest rooms, trains, hotels, industrial plants, similar to that sponsored for a brief period during the war by the Army, Navy, and the United States and local Public Health Services—and under the stress of war emotion accepted without criticism by the medical profession, only to be dropped at the war's end. It is even desirable, I believe, to utilize newspaper advertising in a fashion similar to that of the Public Health Institute of Chicago, though I think that the initiative in this respect should come from a combination of the local health officials and the local medical society. It is unanswerably true that, stimulated by such advertising, many infected persons with early and latent syphilis seek medical advice and attention, who otherwise would come into the hands of the physician, if at all, only after serious late lesions had developed. How many individuals are saved from infection by these patients, or how much money is saved by the prevention of progression through treatment, can only be conjectured, but to anyone familiar with wartime conditions throughout the country, or with the present local situation in Chicago, the saving in both respects would be obviously enormous.

To inject the note of profit into a discussion of medical practice is a heinous sin, the enormity of which I realize. And yet, money, or its lack, is the rock on which even the best instructed medical profession splits in the practical management of the syphilis problem. It is hardly necessary to point out that the treatment of syphilis is expensive, and that, even at depression fees, the minimum cost in private practice of the management of an uncomplicated early case is not less than \$200, and more likely \$350. It is estimated that even in normal times, only 20 per cent of

the infected population can afford to pay for the adequate care of syphilis at the usual private rates; perhaps an additional 50 per cent could meet the cost of care at a pay clinic; and that fully one-third must receive treatment free or for nominal amounts.

As to the 20 per cent under treatment in private practice, would it be amiss to point out to the practitioner that the economic is as important as the medical aspect in planning treatment for the syphilitic patient; that if the patient has only \$100 in all, it would be better for him to go to a free or part-pay clinic at the start rather than after having spent the whole \$100 on 6 weeks of treatment when he needs continuous care for a total of 18 months; that to compensate for the loss of this \$100 revenue, the practitioner might make up as much or more again if he actually looked for more frequently—and found, as of course he would—syphilis in his more well-to-do clientèle? Would it be amiss to suggest that more frequent use of the routine Wassermann would at one time serve the public health aim of uncovering and bringing under treatment the unsuspected syphilitic and the personal aim of improving his own income?

For the 50 per cent who can pay part or all of the actual cost of treatment, but not including a profit for the physician, such facilities as now exist are almost wholly for the lowest incomes of the group. There are many hospital clinics at which treatment is available for a charge of \$.25 to \$1 per visit. Most of these are run on the mass treatment plan, with no privacy, with intermingling of the sexes and races, and under circumstances so distasteful to the more gently born patient as to preclude his regular attendance. For the individual who can afford something better than this, but who is not quite up to the minimum average fee of private practice, there are, with only

three or four exceptions, no facilities whatever available in this country. Such patients are faced with the alternatives of abandoning treatment at private hands because of inability to pay for it, or of accepting the long waits, the hurried attention, the personal indignities of the average part-pay or free clinic. The Public Health Institute in Chicago has blazed a trail which the rest of the medical profession has so far been loath to follow. It has provided first-class professional attention under conditions resembling private practice at a cost level below the minimum attainable in private practice, and yet it has been able to operate either at a profit or at only a small loss. Such clinics should be available in every large center. When possible, they should be conducted under the joint auspices of the local medical society and a large general hospital. They are, of course, anathema to many practitioners, who fear loss of income; but have we not reached a stage in the syphilis problem where considerations of the private practitioner's income are secondary to those of the public health?

Finally, the free clinic services of the country should be largely expanded. In Baltimore, the only clinics which provide completely free treatment are those run by the Health Department. At the general hospital clinics, that run under the auspices of the University of Maryland Hospital (a state institution) is almost entirely pay, a curious and anomalous situation; while that at the Johns Hopkins Hospital is about 70 per cent free and 30 per cent small fee. The city clinics and the Johns Hopkins clinic are completely unable to deal with the problem of the indigent syphilitic with their present facilities; many patients must be turned away without any treatment at all! This is an appalling situation, which cannot be allowed to continue. Money must be found to treat every syphilitic patient, whether or not

he can afford to pay for it himself. This is a civic responsibility which cannot be dodged. Health officers must familiarize themselves with the needs of their communities and must obtain the necessary funds. If unsuccessful single handed, they must invoke the aid of prominent physicians and laymen in bringing to bear the pressure of enlightened public opinion.

What is the community cost, the burden to the tax payer, if the urban health department establishes a division of venereal diseases adequate to provide for Wassermann service to physicians, and free clinic service to all indigent syphilitic patients, whether infectious or not? So far as syphilis is concerned, and leaving out of consideration the cost of care of the frequently associated gonorrhea or chancroid, it is estimated that such a department may be efficiently run for an average cost of \$.60 per patient visit. This estimate includes salaries for administrative and professional personnel, nursing, clerical and social service, the overhead cost of laboratory and clinics, and the cost of drugs and supplies. While it is quite impossible to set definite figures for the average amount of treatment to be given to patients in such widely divergent conditions as seronegative primary syphilis and tabes dorsalis, it is certain that the average patient will not receive more than a total of 40 treatments. Taking this figure, which is probably optimistically high, as the average, and assuming that this amount of treatment is given within one year, the cost per patient per year is \$24. In Baltimore, a city and suburban area of approximately 900,000 people, it is further estimated that there are discovered each year about 9,000 new cases of syphilis, early or late: that approximately 1,800 of these are treated by private physicians, and 3,600 (half of the remainder) at clinics other than those of the Health Department. To manage adequately the re-

maintaining 3,600 (which at present is not being done) would cost the community \$86,400, in place of the \$39,000 now expended. If no privately endowed clinics existed and the entire burden of clinic service were thrown on the community, this figure would be nearly doubled. For the benefit of health officers generally, it is perhaps better to express the probable cost in terms of units of 1,000 syphilitic patients to be treated. The fewer the patients, the higher the cost, because of increased overhead; but I believe that a community cost of \$25,000 per year per 1,000 patients is adequate to provide ample treatment facilities. It is to be noted that this estimate is far below that supplied by Parran in the 1932 *Report of the New York State Health Commission*.⁷

The Medical Society of the District of Columbia has appointed a subcommittee to consider the local venereal disease problem and this committee has submitted a preliminary report⁸ which has been unanimously approved by the membership of the Society. This report, while it refrains at present from making any definite recommendations, clearly suggests in what direction those recommendations when made will be. The report discusses all of the shortcomings of our present haphazard system set forth here and says:

From all of the evidence at hand your committee does not see how we can escape the conviction that this . . . matter must be placed in the hands of the state, so that it can, with the assistance of the medical profession, apply the knowledge already in the hands of the profession to put this disease (syphilis) under control just as it has done other epidemic diseases and just as it would have done with syphilis long ago, had it been an acute infectious disease, instead of a chronic one. Has any plan, short of State control, been successful? The answer is "No." Has any State control plan been successful? The answer is clearly "Yes."

This comment refers, of course, to the enormous reduction in syphilis mor-

bidity accomplished particularly in England and in Denmark; and brought about, it is believed by competent observers, by the nation-wide adoption of one single measure—free treatment for all patients with venereal disease regardless of their ability to pay.

While I am willing to agree with the Washington Committee that all plans of syphilis control so far tried in this country have failed, I am not yet prepared to admit that the medical profession cannot drag itself out of the morass of failure. To do so, however, we need to end the conspiracy of silence among ourselves and with the laity. We need to raise our heads, plunged ostrich-like into the sands of concealment; to bring our problem out into the open; to talk about it among ourselves and with the intelligent laity, not only as a potentially crippling and fatal disease (the spread of which menaces every one of us), but also—since the average individual does not greatly fear physical disaster in the remote future—in terms of dollars and cents. Where the tax payer refuses to become alarmed as to the possibility of his own blindness or insanity 20 years hence, he will wince with pain at an increase in the figure in the lower right hand corner of his tax bill. He can be made to see that \$1,000 spent on the control of infectiousness in syphilis will ultimately save 10 times as much. The public health officer is the physician who must take the lead in breaking down this conspiracy of silence. I believe that he will find the bulk of the medical profession ready and anxious to help him.

In so far as syphilis control is concerned, we are faced with a situation in which we must improve our status both as physicians and as economists. We must effect not only a widespread betterment in the way in which the disease is managed but also in the way in which that management is paid for. Unless we are equal to both of these

tasks, there remain but two alternatives: to continue the conspiracy of silence, to make no progress in the control of the major infectious disease problem; or, by the breaking down of the conspiracy and the awakening of an enlightened public opinion, to see the problem taken from our hands and given over to those of the State. Perhaps one of these two alternatives, both distasteful to all physicians, is inevitable. The effort to avoid them, led by public health officials, is worth the trial.

The President's Committee on Economic Security Appoints a Hospital Advisory Committee

THE Committee on Economic Security of which the Hon. Frances Perkins, Secretary of Labor, is chairman, and Secretary Wallace, Secretary Morgenthau, Attorney-General Cummings, and the Hon. Harry L. Hopkins, director of Federal Relief, are the other members, has asked the following hospital authorities to act as an advisory committee on hospital problems:

- Dr. S. S. Goldwater, F.A.P.H.A., Commissioner of Hospitals, New York City.
- Dr. Frederic Washburn, Director of Public Institutions, Boston.
- Dr. W. S. Rankin, F.A.P.H.A., Director of the Duke Foundation, Charlotte, N. C.
- Dr. Arthur C. Bachmeyer, Member A.P.H.A., Cincinnati General Hospital.
- Dr. Robin C. Buerki, Wisconsin General Hospital, Madison.
- Dr. Michael M. Davis, F.A.P.H.A., Julius Rosenwald Fund, Chicago.
- Rev. A. J. Schwitalla, President, Catholic Hospital Assn., St. Louis.
- Rev. C. C. Jarrell, President, Protestant Hospital Association, Atlanta.

- Mr. Robert Jolly, President, American Hospital Association, Houston.
- Dr. J. Rollin French, President, Western Hospital Association, Los Angeles.
- Dr. Winford H. Smith, Director, Johns Hopkins Hospital, Baltimore.
- Dr. N. W. Faxon, Director, Strong Memorial Hospital, Rochester.

This committee met in Washington on November 20, and an outline of some of the important subjects was presented by representatives of the Committee on Economic Security for the study and counsel of the Advisory Committee. The work of this committee will be of very large value to the entire hospital group, and future plans and future legislation looking to the important problems of hospital care, hospital support, and hospital development will be very carefully considered and such recommendations will be made to the Committee on Economic Security as a close and detailed study of these and other problems will warrant.—*Bull. Am. Hospital Assn.* VIII, 12 (Dec.), 1934.

Natural Immunization to Diphtheria in an Institution *

C. C. YOUNG, D.P.H., F.A.P.H.A., G. D. CUMMINGS, Ph.D.,
F.A.P.H.A., AND M. E. WILSON, M.D.

*Michigan Department of Health, Lansing, Mich.; and Michigan Home &
Training School, Lapeer, Mich.*

PREVIOUS diphtheria studies on institutional populations ^{1, 2} have indicated that a careful study of admission patients would be profitable.

We have observed two groups of patients in the Michigan Home and Training School for 1½ years to determine what effect herding might have upon immunity experience. Records of Schick tests, throat swabs, and blood antitoxin titers have been kept on both groups throughout the observation period.

The first series included 176 patients who had been admitted from 1 to 6 months before observations began. These patients were Schick tested and the antitoxin content of their bloods determined by the Fraser ³ modification † of the Römer test. Schick positive reactors were divided into three groups. The first, or test group, was not immunized; the second and third groups were treated with a sub-standard toxoid ‡ and a standard toxin-antitoxin mixture respectively. Three doses, a week apart, were given. The three groups, together with their Schick nega-

tive controls, were Schick tested, swabbed, and tested for antitoxin at 3 and 9 months after the last dose of antigen.

Observations were made on a second series of 213 patients within 1 month of admission so that institutional influences could be reduced to a minimum. These patients were Schick tested, swabbed, and bled for antitoxin determinations on admission, at 3 and 6 month intervals.

Our studies have revealed the following points:

1. The number of Schick positive reactors in the unimmunized groups was definitely reduced over the test periods and the reduction compared favorably with the reduction in the toxoid group, but not in the toxin-antitoxin group.

2. There were fewer Schick positive reactors than there were patients with blood titers of 0.01 units or below of antitoxin per c.c. at the beginning of the observations.

3. There were a number of Schick negative reactors with 0.002 units or below of antitoxin per c.c. of blood at the beginning of the observation, whose titers were increased at 3, 6, or 9 months.

4. The Schick test behaved as an antigen in some of these Schick negative reactors by raising their blood titers to a level comparable with the negative test.

REDUCTION OF THE NUMBER OF UN- TREATED OF SCHICK POSITIVE REACTORS

The number of positive reactors in the test group of the first series was

* Read before the Laboratory Section of the American Public Health Association at the Sixty-third Annual Meeting in Pasadena, Calif., September 6, 1934.

† Blood sera were tested at four levels, namely, 0.002 units, 0.01 units, 0.05 units, and 0.1 units. Throughout this paper the phrase "or below" means to the next lower level.

‡ Diluted toxoid 6-7 flocculation units per c.c.

reduced by 35 per cent in 9 months. The number in the toxoid group was reduced 50 per cent, and in the toxin-antitoxin group 89 per cent during the same time. The number of positive reactors in the second series was reduced 29 per cent in 3 months, and 39 per cent in 6 months. The results for both series of untreated individuals were therefore comparable. Environmental influence plus the Schick test appeared to be nearly as efficient as the toxoid immunization, but only one-half as efficient as the toxin-antitoxin immunization.

The blood antitoxin titers of those patients whose Schick tests changed from positive to negative increased. There were 19 Schick positive reactors with 0.002 units or below of antitoxin and 3 with more than 0.1 units per c.c. at the beginning of observation. In 3 months, 8 of 22 titers measured more than 0.1 units of antitoxin per c.c., 2 were 0.01 units or below, and 5 were 0.002 units or below. All titers above 0.002 units, and 2 of the 5 0.002 units or below correlated with negative Schick tests. The 3 remaining titers

of 0.002 units or below, remained unchanged at 6 months, but the Schick tests became negative.

The 3 patients with initial positive Schick tests and more than 0.1 units of antitoxin retained the same blood titers for the whole observation period. However, the Schick tests of all 3 were negative at 3 months; but again positive at 6 months.

Series 1	33.2	38.1
Series 2	35.7	51.0

COMPARISON OF INITIAL POSITIVE SCHICK
TESTS AND BLOOD ANTITOXIN
RESULTS

The level at which the Schick test should be positive was taken to be 0.01 or below units of antitoxin per c.c. so as to represent a level of actual measurement. This level is admittedly lower than that commonly accepted (0.03 units). However, it will be seen in Table II that the disagreement between the Schick test and antitoxin titrations would have been even greater if a level of 0.05 units or below had been selected. The difference recorded is therefore conservative. The difference in percentage in the first series is small enough to be statistical, but that in the second series clearly indicates that there must have been a number of Schick negative reactors with 0.01 units or below of antitoxin.

INITIAL NEGATIVE SCHICK TESTS WITH 0.01 OR BELOW UNITS OF ANTI- TOXIN PER C.C. OF BLOOD

Forty-four, or 11.3 per cent, of the 389 patients observed were Schick negative with 0.01 units or below of antitoxin.* All of the Schick negative reactors were still negative at 3, 6, and 9 months, but in 86 per cent of the cases, blood titers had increased markedly at 3 months.

The fact that the Schick test might serve as an antigen was kept in mind throughout this study. When Schick negative reactors with as little as 0.002 units of antitoxin were encountered, it became necessary to determine the part which the test played in the rise in blood titers.

THE ANTIGENICITY OF THE SCHICK TEST

Blood samples were drawn immediately before the Schick tests were administered. Blood titrations were completed before the Schick tests were read and, where possible, additional blood

* The same Schick test toxin and Schick test control were used throughout the study. The Schick toxin was retested to assure us that Schick negative results were not due to impotent toxin. Blood sera with low titers on these Schick negative individuals were repeated to check the first results.

TABLE IV

BETWEEN TIME OF ADMINISTRATION
AND READING OF
NEGATIVE SCHICK TESTS

	0.002 Units or Below	0.01 Units or Below	0.05 Units or Below	0.1 Units	More than 0.1 Units	Total
Admin- istra- tion	14	4				18
Read- ing	4	4	8		2	18

samples were taken at the time of reading. Blood antitoxin titers of 18 patients were determined at the time the Schick tests were administered and when read. Fourteen of 18 individuals showed increases in blood titer between administration and reading. Ten of the 14 showed titers above 0.05 units or enough to agree with the Schick negative readings. In 55 per cent of the cases, therefore, the Schick test itself appeared to be responsible for the negative results. Furthermore, the effect of the test could not be considered temporary because 17 of the 18 patients tested above 0.01 units at the next test.

DISCUSSION

It is well known that Schick positive reactors may become Schick negative in a diphtherial environment. Dudley⁴ has reported a 32 per cent reduction of Schick susceptibles in 3 months in a boys' naval academy in England. This corresponds with the percentage reduction reported here. Dudley found that there was a direct relationship between the number of Schick negative reactors in a group and their epidemic experience. Thus, those students who were present in the academy through two diphtheria epidemics were more Schick negative than those who had been exposed to only one. Both groups were more Schick negative than students on admission. His results indicated that

herd immunization took place only when diphtheria was present in epidemic proportions.

Diphtheria has not been epidemic nor even endemic in the Michigan Home and Training School since 1920, so that the environment of the two schools cannot be compared. The population of the school has been artificially immunized with the exception of the patients reported here.¹ The diphtheria bacilli isolated from patients hospitalized with septic sore throat, Vincent's angina, and from our concurrent throat cultures have been of low virulence or avirulent. This indicated that possibly herd immunization was taking place continuously through the medium of organisms of low grade virulence which had lost their ability to cause clinical diphtheria.

The carrier rate for the school has not been determined since 1920 (1.9 per cent). All patients are hospitalized upon admission, and routine throat swabs are taken. It is, therefore, possible to determine carrier rates for admission and hospitalized patients. In 1932, 3.5 per cent of hospitalized individuals (including admissions) were carriers, while the rate for 1933 was 2.9 per cent. These rates were probably lower than those for the whole institution. Dudley² has shown that 40 per cent of a group of boys were carriers for short intervals over a period of a year, while the carrier rate was 6.9 per cent, indicating that the rate does not measure the total of individuals infected over a given period.

Diphtheria bacilli were found in the throats of 2 untreated Schick positive individuals whose test eventually became Schick negative. We observed a third individual whose negative Schick test coincided with the presence of diphtheria bacilli in the throat. There had been 3 positive Schick tests at 3 month intervals before hospitalization. Five months after the last positive test,

this patient was committed to the hospital with a sore throat. The virulence pig did not die, but there was some evidence of a toxemia. The Schick test was negative. Diphtheria bacilli were not isolated from the balance of the patients whose Schick tests became negative.

We did not anticipate the discovery of the Schick negative reactors with less than 0.002 units of antitoxin. It was not possible to explain the presence of such small amounts of antitoxin in terms of herd immunity. The fact that the Schick test stimulated antitoxin production in certain of these individuals helped to keep the results obtained on a sound basis and indicated the immunological behavior of such a group in the presence of diphtheria. Their response to a given antigen would be so rapid that the emergency could be easily handled.

The effect of the Schick test on the antitoxin titer of Schick negative reactors suggests that the change from the Schick positive to the Schick negative state might be accomplished in the same manner. Would it not be possible for the Schick test or a series of Schick tests to cause a rise in blood titer which would result in a negative test? Glenny³ has indicated the marked effect of the secondary stimulus in the production of antitoxin. It seems more reasonable to assume that the primary and secondary stimuli have been supplied by diphtheria bacilli of some virulence and that a Schick positive individual might then become negative in response to a low grade infection or to a series of Schick tests. This type of Schick positive individual would fall into the group designated by Glenny³ as the Schick positive immune, that is, an individual whose response to an antigen was secondary with a rapid rate of immunization. It is our intention to study a group of individuals by observing blood antitoxin titers uninfluenced by the Schick test. A rise in

blood titer would then be directly attributable to environment.

It will be recalled that the toxin-antitoxin mixture appeared to have twice the immunizing power of the toxoid. The interpretation of these results must be qualified by the knowledge that a certain number of individuals would have become Schick negative without treatment. This in turn indicates that certain individuals are easier to immunize than others and that a preponderance of this type in one group and not in the other would radically alter the end results. We would then have to credit the individual and not the antigen. Quoting Glenny ⁵: "Such a statement as 'a single injection of a given antigen has rendered a man Schick negative in 6 days' is to be put to the credit of the man probably more than that to the antigen." The Schick positive reactors who became

Schick negative in the series reported, did so over a relatively short period. If the effects of herd immunization are such that a certain number are easily immunized while the remainder are only immunized through diphtheria or artificial immunization, then it is logical to assume that this remainder might serve as an excellent group for the comparison of antigens.

SUMMARY

At the Michigan Home and Training School at Lapeer 389 patients have been observed by means of the Schick test, throat swab, and blood antitoxin titration at 3, 6, and 9 month intervals for evidence of herd immunization.

The number of Schick positive reactors in two series of patients was reduced 32 per cent at the end of 3 months without treatment.

Of 389 patients 11.3 per cent were

CHART I

REDUCTION OF SCHICK POSITIVE REACTIONS FOLLOWING
HERD OR ARTIFICIAL IMMUNIZATION

Schick negative, with 0.01 units or below at the beginning of the observation. Eighty-six per cent of the blood titers in this group had increased in 3 months.

CONCLUSIONS

The number of Schick positive reactors in a group is reduced by herd immunization over a relatively short period. A certain number of individuals exist whose antitoxin titer is too low to agree with their negative Schick test. These have the ability to respond rapidly to diphtherial antigen.

A comparison of artificial antigens should be carried out upon a group of Schick positive reactors with similar diphtherial history.

Wallace Will Fight for New Food and Drugs Bill

IN his annual report to the President—a document modest in size as judged by usual Government standards, consisting of only 119 pages—Secretary Wallace breaks the news that he, Professor Tugwell and others will enter the ring once more during the coming session of Congress in an effort to secure the enactment of a new food and drugs act. This is not exactly a sur-

prise, a semi-official announcement to the same effect having been made in *Printers' Ink* [Dec. 6].

But it is interesting as showing the Secretary's line of reasoning and indicating to merchandising interests that, whether they like it or not, some sort of bill is reasonably sure to be made law. . . . —*Printers' Ink*, Dec. 13, 1934.

Sources and Modes of Infection in Two Family Outbreaks of Syphilis*

A. L. GRAY, M.D., AND W. H. CLEVELAND, M.D.

*Epidemiologist, Mississippi State Board of Health, Jackson;
and Health Officer, Lee County, Tupelo, Miss.*

ACCORDING to Rosenau, syphilis was unknown before the year 1493. Within a few years after that date, it had an astonishing spread over the known world. It has continued its spread, retarded but little in its progress, in the human races. This, the great imitator, has been one of our greatest causes of suffering and an important cause of death.

Its clinical manifestations are well known, and the tremendous progress with regard to the treatment of the disease has been made within the present century. The social problems need no particular discussion. It is unfortunate, however, that this disease is too often thought of by both physicians and laymen as a venereal disease; and it is also unfortunate that treatment and the handling of the case is often clouded by the moral connotation attached to the word venereal. It would be far better if the common name for syphilis were greatpox and it were handled, at least from the point of view of the investigation of the source, as smallpox is handled. Too many of us as physicians have been content with reporting the case and then getting it under treatment, without being concerned with the possible source of this individual case, and with little thought to future cases of which the one under consideration

may be the source. Consequently, epidemiological investigations are rarely followed through in the hope of preventing further spread of the disease.

That this disease lends itself to the finding of sources of infection in the form of missed as well as known cases even more readily than does typhoid fever and other communicable diseases, is agreed to by many authorities. It is true that much less has been accomplished in dealing with it as to locating sources of infection than in the case of some other communicable diseases.

This paper is presented to call attention again to some of the sources and modes of infection of syphilis, and as an illustration of what may be accomplished in an epidemiological study of cases as they present themselves to physicians and health workers. The sources and modes of infection in the 2 family outbreaks as related below should recall to our minds that this disease has other methods of spread than through sexual intercourse and congenital acquisition, which may and probably often do play a major part in the propagation of the infectious agent within a family or community.

FAMILY OUTBREAK NO. I

In October, 1933, while making school inspections, the attention of the county health officer of Lee County, Miss., was called to a boy of the R.

* Read before the Epidemiology Section of the American Public Health Association at the Sixty-third Annual Meeting in Pasadena, Calif., September 3, 1934.

family with an eruption. He was attending a rural school at the time. Upon examination, he presented what was apparently a typical generalized secondary syphilitic eruption. Communication with his parents resulted in a visit by the R. family to the office of the health officer. A study of the situation revealed that 6 of 10 members of this family had syphilis, the diagnosis of each case being confirmed by a blood Wassermann. Before the mode of entry of the infection into this family was determined, the father and mother accused each other of breaking the marital contract. When the investigation was completed, the following picture was gotten together:

In the R. family, A. R., female, age 17, began having sexual intercourse with a neighbor boy D. H., in November, 1931. D. H. had been in the health department office in July, 1931, at which time he had a chancre on the penis. Blood Wassermann on D. H. at this time gave a 2+ reaction. At the time of investigating this outbreak, D. H. could not be found.

A. R. gave a history of having had intercourse with D. H. at frequent intervals beginning about November 1, 1931, and continuing until June, 1932. She denied having had intercourse with anyone other than D. H. She gave no history of having had a primary lesion except for a period of about 1 month. In April and May, 1932, she had burning on urination in what was apparently the posterior wall of the vaginal orifice. It is probable that this burning was at the site of the initial lesion although no physician saw it.

About August 1, 1932, she developed what was apparently secondary lesions in the form of mucous patches on the mucous membrane of the throat, tongue, and gingivae. These were present for about 2 months but were not observed by a physician.

While A. R. had secondary lesions in

her mouth, she masticated food and gave it to her brother, G. R., age 2, who developed a chronic sore on the mucosa of the lower lip about September 1, 1932, which persisted for 3 or 4 weeks. He developed a generalized eruption November 26, 1932. He was still nursing at the breast of his mother, Mrs. R., at the time of occurrence of the sore on his lip and continued to do so until about March 1, 1933. Mrs. R., age 38, developed a chronic sore on one of her nipples in November, 1932, which was about 2 months after the sore appeared on the lip of her baby, G. R. She was told by her physician that this lesion, which persisted until March, 1933, was probably cancer. In April, 1933, Mrs. R. developed chronic sores about her vagina and in her mouth, which did not heal until the latter part of August of the same year. She had no generalized eruption.

Mr. R., age 40, developed a chancre on the penis July 1, 1933. This began healing only after treatment was started in November. He developed no secondary lesions.

B. R., male, age 8, was the school child from whom the investigation started. A history was obtained to the effect that A. R., the initial case in the family, gave this boy some gum which she had been chewing, transferring it directly from her mouth to his mouth. This occurred while A. R. had secondary manifestations in her mouth, which was from August 1, 1932, to January 15, 1933. Beginning about February 20, 1933, and continuing for about 1 month, B. R. complained to his parents of having a sore on the mucous membrane of his cheek. At the time of the investigation, a scar about 1 cm. in diameter was observed at the site indicated as being the location of the sore which was at the level of coaptation of the teeth opposite the first molar. He developed a secondary generalized eruption October 12, 1933.

FIGURE I

ILLUSTRATION SHOWING SOURCES AND MODES OF INFECTION IN OUTBREAK No. 1

L. R., female, age 4, gave no history of a primary lesion. However, she was also favored with some of the second-hand gum at the same time as her brother, B. R. She developed a generalized secondary eruption about

October 20, only a few days after the secondary eruption became manifest in B. R. It is probable that she got her infection through the gum at the same time as her brother, B. R. A. R. stated that she divided the gum which she

was chewing, giving one portion to B. R. and one to L. R.

To demonstrate more vividly the sources and modes of infection in this outbreak of syphilis, a graphic representation is given in Figure I.

A. R., the initial case, had a miscarriage November 26, 1932, delivering a fetus of about 6 months.

There were 4 other boys in the family, 6, 10, 15 and 19 years of age, all of whom had negative blood Wassermanns in October, 1933, when the investigation was started. There were no clinical symptoms in any of these.

Mrs. R. delivered apparently normal twins in April, 1934.

FAMILY OUTBREAK NO. 2

In the study of Outbreak No. 1, the investigators were led to the D. family because the attending physician of these two families felt that the original of 3 cases in the D. family probably got his infection from D. H., who infected the R. family. However, it was found that D. H. did not introduce the infection into the D. family.

Mr. D. with 2 neighbor boys went to Arkansas in early September, 1932, to pick cotton, and while there stayed in the same home. C. F., one of this trio, had been seen a few months earlier by the physician who attended the R. family mentioned in the discussion of Outbreak No. 1. Upon coming to this physician, C. F. presented a primary syphilitic lesion, the diagnosis of which was confirmed by a blood Wassermann. While the 3 were in Arkansas and for about 2 weeks prior to their going to this location, C. F. had a chronic sore throat for which he used a local application. This was probably a secondary lesion, but no physician saw him and made that diagnosis.

During their stay in Arkansas, these 3 individuals shaved only on Sunday mornings, using the same razor in rapid succession. Upon one occasion, Mr. D.

cut his chin slightly. He returned home early in October, and during the first 2 weeks in November developed a chronic sore at the site of the cut, which became about $\frac{1}{2}$ inch in diameter and persisted for more than a month. On January 1, 1933, he developed a generalized eruption which was diagnosed as measles, but which persisted until 3 weeks later when anti-syphilitic treatment was started. Mr. D. vehemently denied having had any sexual association with anyone from whom he might have gotten the infection.

Mrs. D. gave no history of having had a primary lesion. However, she developed secondary manifestations about February 15, 1933, consisting of a protracted sore throat accompanied by lesions of the tongue and gingivae.

While Mrs. D. had secondary lesions in her mouth, she masticated food daily and gave to her baby, age 3. This child had what was apparently a chancre on the tip of its tongue, beginning about March 20. When the investigation was made, there was a large scar at the site of this lesion.

The diagnosis in each of these 3 cases was confirmed by a blood Wassermann. Three older children in this family had a negative Wassermann and had had no clinical symptoms of syphilis at the time of the investigation.

In both of these outbreaks some of the epidemiological evidence as to sources and modes of infection was circumstantial. All information obtainable at the time of investigation, however, indicated that they were as outlined.

SUMMARY AND CONCLUSIONS

Family Outbreak No. 1—Case No. 1 was apparently infected by a neighbor boy by sexual intercourse. She apparently transmitted the infection to her baby brother by feeding it food which she had masticated while secondary lesions were present in her mouth. This child, case No. 2, had a

chancre on its lower lip, and, by nursing at her breast, infected its mother, case No. 3, who developed a chancre on her nipple followed by secondaries in her mouth and vagina. Case No. 4 developed a chancre on the penis apparently getting the infection from case No. 3, his wife. Case No. 5 was apparently infected by case No. 1, his sister, by chewing gum which she had chewed, resulting in a chancre on the mucous membrane of his jaw. Case No. 6 also chewed some of the same gum at the same time as case No. 5 did,

and developed secondaries at about the same time as case No. 5. No history of a primary lesion in this case was obtained.

Family Outbreak No. 2—Mr. D. was apparently infected through a cut by a razor used by a known case of secondary syphilis, a chancre developing at the site. Mrs. D. apparently became infected through sexual intercourse with Mr. D. She masticated food for her baby while secondaries were present in her mouth and the baby had the initial lesion on the tip of its tongue.

Active Immunization Against Poliomyelitis*

MAURICE BRÖDIE, M.D.

*Bureau of Laboratories, Department of Health, City of New York, and
Department Bacteriology, New York University and Bellevue
Hospital Medical School, New York, N. Y.*

THE problem that confronts the medical world concerning poliomyelitis is, What can be done for its prevention, or treatment in the acute stage, in the hope of warding off paralysis? In the treatment of the acute stage, we are no further advanced than when Heine described the disease as a clinical entity in 1840. In 1910, when Netter *et al.*¹ first announced that convalescent serum neutralized the virus of poliomyelitis, great hope was held that it had curative powers. Many reports have favored its use. However, as I have pointed out,^{2a} several significant controlled studies have failed to uphold its value. Moreover, our own experimental studies on monkeys showed that large amounts of convalescent serum or whole blood had no appreciable effect upon the progress of the disease, even if given during the earliest stages. The reason for this is obvious from studies on the pathogenesis of the disease, which show that it is confined to and transmitted along the nerve tracts of the central nervous system^{2b} by certain cells by which the virus is absorbed. This renders it highly improbable that the serum reaches the virus.

To prevent the epidemic spread of

the disease by means of isolation is difficult, for it apparently spreads mainly through carriers and abortive cases. As judged by the results of Davide³ and Brebner,⁴ passive immunity obtained by the use of convalescent serum offered some hope, but a recent report from California does not seem to justify this. Moreover, the serum is expensive and the immunity, if present, lasts for only a few weeks. Therefore, in view of the present state of knowledge and the difficulty in controlling the disease by other means, a safe and effective active immunization of the susceptible age group offers the most hopeful means of combating it, especially if immunity can be produced rapidly.

Experience with other virus diseases points to 3 possible methods of immunization. The first of these is by the use of an active virus which, through adaptation to one species, is non-infective for another, yet gives immunity to that species. Perhaps the best example of this is vaccinia virus. The second is by a combination of virus and serum, using an incubated mixture of active virus and antiviral substance, *e.g.*, yellow fever vaccine; or giving virus and serum separately, as in the case of cattle plague. The third method involves the use of germicidally inactivated virus, as in the case of dog distemper, foot and mouth disease, cattle and fowl plague, and rabies. Heat killed virus

* Read before the Laboratory Section of the American Public Health Association at the Sixty-third Annual Meeting in Pasadena, Calif., September 3, 1934.

has not proved satisfactory for the prevention of virus diseases.

In our experiments, the various methods of active immunization were investigated. *Macacus rhesus* monkeys were injected intracutaneously, in the abdominal wall, with the antigens. Some of the virus infiltrated into the deeper layer of the skin. Unless otherwise stated, a 10 per cent suspension of infective cord tissue was used prepared as previously described.^{6, 8} Similar concentration of virus suspension and methods of inoculation were used in the human cases.

Immunity was tested for some 3 to 6 weeks later by inoculating virus intracerebrally into the treated animals, and by testing for antibody by the neutralization test, which consists of mixing 0.9 c.c. of the serum with varying amounts of virus, incubating for 2 hours at 37° C., and after 8 to 10 hours on ice, injecting intracerebrally into other monkeys. In all instances, the neutralizing power of the serum or the resistance to direct intracerebral injection was estimated in terms of M.C.P. (minimal completely paralyzing) dose, which consists of the smallest amount of virus-containing-tissue causing a complete and rapid paralysis in *Macacus rhesus* monkeys weighing from 2.5 to 4 kilos, within 13 days after intracerebral inoculation of virus.⁵

Since the monkey is the only known experimental animal that is susceptible to the virus of poliomyelitis, one cannot determine whether monkey fixed virus is infectious for man except by direct inoculation, which is attended by risk. In the monkey, active virus produces considerable immunity the degree of which is proportional both to the size⁶ and infectivity of the dose.⁷ It was found that cord tissue harvested at the height of paralysis gave a better immunity than that obtained later, and a better protection than any other part of the cerebrospinal axis. However,

active virus proved to be dangerous, for occasionally animals developed mild non-paralytic and even severe paralytic forms of the disease. In some animals immunity developed in the absence of any tissue reaction as indicated by an absence of symptoms, cerebrospinal fluid, pleocytosis, or temperature changes during the course of immunization.

The specificity of the immunity was demonstrated by the fact that animals which received non-infective cord tissue failed to develop immunity.

The dangers attending the use of active virus in the monkey precluded its use in the human. Work on virus-serum combinations was carried out in conjunction with Dr. Alton Goldbloom, McGill University. The virus-serum combinations were given either as an incubated mixture, or separately, in which case the virus was administered intracutaneously and the serum subcutaneously, either before, with, or after the virus.^{8a} Both methods of administration gave immunity, and in the latter it was found that serum preceding virus gave a lower immunity than when administered with or after the virus. Further experimentation^{8b} showed that an excess of serum, that is, more than was required to prevent infection, reduced the immunity considerably. Inasmuch as the virus in serial passage changes in potency and since batches of convalescent serum are of different strengths, each must be titrated to arrive at a satisfactory balance. This entails the use of a considerable number of monkeys, rendering this form of immunization impractical.

The results with germicidally treated virus are rather contradictory. Phenolized virus has been reported to be dangerous and unreliable in its efficacy by some,^{9a, b, c} whereas Kraus¹⁰ and Erber and Pettit¹¹ reported favorable results. However, from the data presented, the virus used by the latter did

not appear to have been inactivated. Abramson and Gerber,¹² Römer¹³ and Jungeblut and Engle¹⁴ failed to demonstrate immunity with formalized virus.

The results of Abramson and Gerber¹² with heat killed virus and the results of Kraus¹⁰ and Erber and Pettit¹¹ suggest that the possibilities of vaccination with inactivated virus be reinvestigated. This is further borne out by the results obtained with

germically treated antigens in other virus diseases.

Throughout this work, the infectivity of the virus was checked by repeated intracerebral and intraperitoneal inoculation of large amounts of the germically treated virus. To inactivate virus, various concentrations of the germicide were mixed with the virus and kept either at ice box or incubator temperature. In each instance, double

TABLE I

Concentration of Cord Per cent	M.C.P. Dose Injected Intracerebrally	Temperature Ice Box (Centigrade)	Days of Contact between Virus and Germicide	Result

the required amount of germicide was added to a 20 per cent cord suspension and, during the period of contact, the mixture was agitated frequently.

EFFECTS OF GERMICIDES UPON THE VIRUS OF POLIOMYELITIS

It was planned to treat virus suspension with merthiolate, ether, phenol, and formalin, and keep at ice box temperature. However, both merthiolate and ether were discarded because the virus was quite resistant to their action. Phenol in 2 per cent concentration appeared to inactivate the virus after 10 days.

A mixture of 0.3 per cent formalin and 10 per cent active cord suspension was tested after contact of 1.5 to 11 days at ice box temperature and was found to render the virus non-infective after 3 days. To test for virus in these mixtures, large amounts were repeatedly injected intracerebrally and intraperitoneally into *Macacus rhesus* monkeys. Careful observations of the animals, daily temperature readings, and frequent spinal fluid examinations were carried out, and only when all were negative, was the virus designated non-infective. This is demonstrated in Table I.

ACTIVE IMMUNITY EXPERIMENTS IN MONKEYS

A preliminary experiment showed the formalized virus to be superior to the phenolized, the latter being a cord suspension treated with 2 per cent phenol and kept at ice box temperature for 10 days. The animals received either 1 or 2 doses of the formalized virus, the second being given at 10 to 20 days after the first.

Experiments were then conducted with cord suspension treated with 0.3 per cent formalin for 10 days at ice box temperature, to determine the following points:

1. The best immunizing dose, by injecting animals with 2.5, 5, and 10 c.c. amounts, respectively

2. The comparative value of 1 and 2 doses, using 2.5, 5 and 10 c.c. amounts

3. The relative immunity produced with active and formalized virus

The summary of results is as follows:

1. Of 3 animals that received 2.5 c.c. of formalized virus, only 1 had demonstrable tissue immunity. All had neutralizing substances in their blood sera.

2. Of 12 animals given 5 c.c., 2 failed to show demonstrable tissue immunity, while 2 had a slight degree of immunity. Seven had a tissue immunity equal to or better than that developed by animals receiving a similar amount of active virus. All but 1 of the animals showed neutralizing substances in their sera.

3. Two of 11 animals inoculated with 10 c.c. of formalized virus failed to show a demonstrable tissue immunity. Only two showed resistance to direct intracerebral inoculation of virus comparable with that of the majority of animals which received 5 c.c. of the same material. Humoral immunity was present in the sera of all but 2 animals.

Thus 5 c.c. amounts appeared to give the best results. The use of 2 doses of antigen did not appear to be better than 1.

In the previous experiments 0.3 per cent formalized suspension was used after 10 days' contact with the virus, though it is inactivated after 3 days. In the present experiment, virus that had been in contact with the antiseptic for only 3 days was used. Eight animals were given 5 c.c. of a 10 per cent suspension—4 received a single dose, the others 2 doses 11 days apart.

The results obtained with material formalized for 10 days are given in Table II, and those of virus suspension formalized for 3 days in Table III. There is no obvious difference in the results. Thus, if at ice box temperature formalin is permitted to act for a longer time than necessary to inactivate the virus, it does not reduce its immunizing power.

The degree of tissue and humoral immunity obtained in 20 animals receiving 1 or 2 doses each of 5 c.c. of the

(b) that of convalescent monkeys. The latter group consisted of 5 animals which had definite paralysis, 4 with considerable residual paralysis and 6 others that showed clinical manifestations of the disease, with or without paresis. The results are summarized in Table IV.

It is evident from this table that the degree of tissue resistance developed by animals given formalized virus compares favorably in at least half the animals with that developed by animals given like amounts of active virus. Moreover, in half of the animals, the immunity compared favorably with animals recovered from a severe attack of the disease. Almost all the monkeys had a better immunity than those recovered from mild attacks of poliomyelitis.

On the other hand, the degree of humoral immunity was much lower in animals treated with formalized than with active virus and also lower than that of monkeys recovered from severe attacks of the disease, but decidedly better than that of animals recovered from a mild attack of the disease.

These experiments have demonstrated conclusively that an appreciable immunity can be developed by formalized virus, as indicated by the resistance of the animals to direct intracerebral inoculation of virus and the presence of antiviral substances in the blood stream.¹⁵ Because of the amount of skin irritation, and even necrosis, resulting from the formalized antigen, it was decided to use lower concentrations of formalin at incubator temperature. Ten per cent cord suspensions were treated with 0.1 per cent and 0.2 per cent formalin, respectively, at 37.5° C. The former concentration of antiseptic inactivated the virus in 12 hours and the latter in 6 hours.

Eleven animals received either 1 or 2 doses each of 5 c.c. of 10 per cent suspension inactivated with 0.2 per

formalized vaccine, was compared with: (a) that developed by animals receiving similar amounts of active virus, and

cent formalin. Five received that which had been kept at incubator temperature for 6 hours, the minimum time required to inactivate the virus, the other 6, virus suspension formalized for 24 hours. The animals receiving the formalized cord suspension, treated just long enough to inactivate the virus, developed an immunity quite comparable with that developed by those receiving virus suspension, inactivated at ice box temperature. However, the animals that received the over-treated virus (0-2 per cent formalin for 24 hours) developed less immunity.

Another lot of 6 animals received 2 doses each of 5 c.c. of virus suspension treated with 0.1 per cent formalin for 24 and 72 hours respectively. Five of the 6 resisted direct intracerebral inoculation of 1 or more infective doses of virus, and all showed some humoral immunity. There was no appreciable difference in the degree of immunity produced by 24 or 72 hour treated virus suspension. In both, the virus was over-treated and the degree of immunity was slightly lower than usual.

Although the number of animals is small, this work suggests that the virus should be in contact with the antiseptic for just the amount of time necessary to inactivate it in the incubator. Inactivated at ice box temperature, an addi-

tional week of contact between virus and germicide, does not diminish its antigenic power. Whether virus emulsion inactivated at ice box temperature could be stored for long periods, or whether when inactivated at incubator temperature, it can then be stored on ice, must be determined.

The 0.1 per cent formalized suspension gave but little skin irritation.

In the course of this work certain differences in the immunological response of animals to active and formalized virus were found:

1. The degree of immunity in the case of active virus was proportional to the size of the immunizing dose, the optimum response being obtained with 10 c.c. amounts; while with formalized virus, this relation was not definite, for 5 c.c. seemed as good if not better than 10 c.c. amounts.

2. With active virus, the degree of humoral immunity was decidedly higher than that of tissue immunity, as demonstrated by a comparison between the number of infective doses of virus neutralized by the animal's serum and the number the animal resisted by intracerebral inoculation. Therefore,^{8a} humoral immunity is more easily detected than is tissue immunity. With the use of inactivated virus, although the degree of tissue immunity obtained with 5 c.c. amounts often equalled that produced by a like amount of active virus, the neutralizing power of the serum was decidedly lower. Occasionally, in animals immunized with formalized virus, the tissue immunity was greater than that of the serum. In the case of active virus, there was usually

ANTIBODY CURVE 1

a correlation between the humoral and tissue immunity, not evident in the case of the formalized antigen. Normal cord tissue fails to induce the production of neutralizing substances for the virus of poliomyelitis. This tends to rule out the possibility that the higher neutralizing power produced with active virus may be due in part to a nonspecific substance elaborated in response to the injection of normal cord, and which is rendered inert by formalin.

3. Two doses of active virus, when properly spaced, gave decidedly better immunity than a single dose, but, using formalized antigen, 2 doses did not appear to be superior to 1 dose.

The next step was to determine the first appearance and then the subsequent rate of development of immunity. Inasmuch as the humoral immunity is decidedly higher than tissue immunity in animals receiving active virus, and since they correlate, it was decided to carry this out by following antibody curves in animals receiving active virus. After determining that the blood serum of monkey No. 380 had no neutralizing power for the virus of poliomyelitis, it was given intracutaneously approximately $\frac{3}{4}$ of a skin infective dose. Serum was collected after 2, 6, 10½, 16, 20, 30 days, 6 and 13 months, respectively, and the neutralizing power tested. The results are shown in Graph 1.

Following a period of at least 6 days, during which no antibody was demonstrable, it became evident between the 6th and 10th days, reaching its height by the 20th day, after which the

neutralizing power of the serum diminished so that after 6 months it was approximately $\frac{3}{4}$ and after 13 months $\frac{1}{6}$ of the maximum titre. At the end of 2 years immunity was still demonstrable. To confirm these findings, a second animal, whose serum showed no antibody, received approximately $\frac{1}{2}$ a skin infective dose. The results, given in Graph 2, confirm those of the first animal in showing a lag of about 6 days, with demonstrable antibody between 6 and 10 days, reaching its height about the 20th day. This animal maintained its full immunity for at least 10 months.

To determine the optimum time for giving the second dose, each of 4 animals, whose serums had no neutralizing power for the virus, received approximately $\frac{3}{4}$ of a skin infective dose of virus. Each monkey received a second inoculation given 6, 10, 14, or 20 days later. (As in the preceding experiments, the animals were bled at various intervals during the course of immunization and the serums were tested for virus-neutralizing substances.) The results, given in Graphs 3, 4, 5, and 6, show that when a second inoculation is given during the refractory period following the first, it does not produce much additional immunity, but given during the rise or height of antibody response to the first, considerable additional protection follows, especially if given during the rise.

Thus it seems that antibody develops

ANTIBODY CURVE 2

ANTIBODY CURVE 3

ANTIBODY CURVE 4

ANTIBODY CURVE 5

ANTIBODY CURVE 6

on the 6th day after inoculation, or soon after, and reaches its height in approximately 20 days. The best interval for the 2 inoculations is between 10 and 14 days. At present the only method of determining the success or failure of vaccination is the direct intracerebral test or the demonstration of antiviral substances in the animal's serum. Therefore, the erythrocytic sedimentation rate was followed in a series of 18 monkeys. The tests were carried out between the 7th and 20th days after the administration of antigen, the period during which immunity develops. It was found that of 15 animals which developed resistance to intracerebral inoculation of virus, 13 showed an increased red cell sedimentation rate. None of the 3 animals that failed to develop such immunity showed any change in the sedimentation rate. Inasmuch as the increase in rate might develop at any time between the 7th and 20th days, too many determinations would be required for practical purposes.

The animal experiments had shown that virus suspension inactivated with 0.1 per cent formalin was not only antigenic but also produced no harmful systemic or local reaction. Before attempting to apply it to the human, it

was necessary to determine whether the virus fixed for monkeys protected against recently isolated human strains. The literature upon this point is inconclusive. Burnet and Macnamara¹⁶ suggested that the strain isolated from a case in Australia differed antigenically from the animal passage strain they used, while Smith and McKie¹⁷ maintained that only differences in the virulence of the strains existed. On the other hand Weyer,¹⁸ Paul and Trask,¹⁹ and Flexner²⁰ suggested that there were immunological differences between recently isolated and monkey passage strains. However, Flexner²⁰ found that although differences existed, the passage virus protected against the recently isolated strains.

Therefore, animals actively immunized and convalescent from attacks with the Fl. monkey passage virus were inoculated with 2 recently isolated strains, 1 of which had undergone 3 and 4 passages through monkeys, and the other 1 passage. The tests were carried out quantitatively in terms of M.C.P. doses of virus suspension.

The sera of 2 animals actively immunized and of 1 monkey convalescent after infection with the passage strain were tested against 1 strain. A definite

quantitative difference was found between this strain and the passage strain, for the serum neutralized approximately only 1/10 as many infective doses of the recent passage virus as of the fixed virus. However, the convalescent animal showed no effects after the intracerebral injection of 5 M.C.P. doses of recent virus. One of 3 animals immunized with the Fl. virus and 3 convalescent animals showed a resistance to direct intracerebral inoculation of multiple infective doses of the second recently isolated strain. These findings are in keeping with those of Flexner²⁰ and indicate that the monkey passage virus immunizes against recently isolated strains, but that there is a quantitative difference. This appears to be more manifest in the humoral than in the tissue immunity.

It was then decided to test the vaccine on human beings. Before doing so on children, it was deemed advisable to try it upon ourselves, not that we had misgivings about the possibilities of infection, but to determine whether it would produce any disagreeable local or general reactions. Six volunteers from the Bureau of Laboratories were given 5 c.c. doses of 10 per cent virus suspension inactivated with 0.1 per cent formalin for 16 to 48 hours. Three were given 1 dose, 2, 2 doses, and 1, 3 doses. The second inoculation was given 11 days after the first, and the third, 8 days after the second. Those given a single dose were inoculated subcutaneously, while those given more than 1 inoculation received 1 to 2½ c.c. intracutaneously, the remainder subcutaneously. At the time of inoculation there was some soreness lasting but a few minutes and probably due to the formalin. Three of those injected had some induration for a few days, not painful or uncomfortable. No systemic or untoward reaction developed.

The blood sera of all 6 obtained before immunization were tested for anti-

body and the amount was determined by careful titration. Tests are now in progress to determine whether blood sera obtained between 3 and 4 weeks after immunization showed increased antibody. A preliminary determination on the sera of the 3 receiving more than 1 dose of vaccine suggests an increase. This must be rechecked and the amount of additional antibody must be calculated. The results on the other 3 have still to be obtained and when complete data are on hand, a comparison between the efficacy of 1, 2, and 3 doses will be available.

It was now evident that the vaccine could be administered with perfect safety and so it was given to 12 children, aged 1 to 6 years. Prior to the vaccination, the children were bled in order to determine the amount of antiviral substance in the serum of each.

The virus suspension used for preparation of the vaccine was cultured aerobically and anaerobically before it was treated with 0.1 per cent formalin for 16 hours, 12 hours being the time required to inactivate the virus. Five received a single dose of 5 c.c.; the others were given a second dose, either 11 or 13 days later. One to 2½ c.c. were given intracutaneously, the remainder subcutaneously, in the skin of the abdominal wall.

The children were observed for local and general reactions and temperatures were recorded 4 times daily. There was no apparent general reaction or discomfort and at no time any febrile manifestations that could be attributed to the vaccine. The amount of local reaction was negligible, consisting only of some induration in those receiving the larger amounts intracutaneously. Those receiving a second dose were not rendered sensitive by the first. The bloods were collected at 3 and 4 weeks after the beginning of immunization.

In each instance 0.9 c.c. of blood serum obtained in the control period was

tested against small amounts of virus to determine the level of neutralizing substances before immunization. The sera obtained 3 weeks after vaccination were tested in triplicate, against 40 to 120 infective doses of virus with simultaneous titrations of the virus as controls.

Table IV gives the age and weight of the children, the course of immunization, the antibody content of the sera in the control period and the results of the bleeding after 3 weeks (19 days in the case of K. S. and A.) as far as they have been completed. All 12 children showed the production of appreciable amounts of antibody or antiviral substances. So far, 2 sera have neutralized at least 40, 3 at least 80, and the other 7 at least 100 infective doses of virus.

Immunity was obtained by either 1 or 2 injections. It is too early to state which will give the greater protection. Whether or not the level of neutralizing substance in the control period affects the degree and rapidity of antibody production produced by the vaccine has still to be determined.

The antibody production was decidedly greater in the children than in the monkeys. If the vaccine which produces a relatively high tissue, but low humoral immunity in the monkeys acts similarly for human beings, the degree of protection obtained in these children should be quite appreciable.

Of course we have no index as to the level of immunity required to protect the children against natural infection nor whether the immunity obtained in these is sufficient. The tissue immunity in children cannot be tested, but as the monkeys treated with formalized virus showed a relatively high tissue immunity, sufficient in most cases to withstand intracerebral inoculations of virus, it is quite likely that the children have an appreciable tissue immunity. By analogy with louping-ill,²¹ a disease of sheep quite analogous to polio-

myelitis, it should be ample to protect against natural exposure to the virus, for formalized louping-ill virus was unable to protect sheep against intracerebral infection, yet did against the natural disease.

SUMMARY AND CONCLUSIONS

Of the various methods tried in *Macacus rhesus* monkeys, for the production of active immunity against the virus of poliomyelitis, virus suspension inactivated with formalin proved most satisfactory. Either 1 or 2 doses gave appreciable immunity and the degree compared favorably with the immunity developed by active virus or after convalescence. Five c.c. appeared to be a satisfactory dose.

A series of adults and children were then given the vaccine without any untoward local or general manifestations. It was shown that the vaccination gave an appreciable antibody response in the humans.

Whether or not the immunity is lifelong has still to be determined. Although longer intervals were not tested in the monkeys, immunity was present after 3 months with formalized virus and 2 years with the active virus.

Imagination in Public Health

" . . . It is inconceivable that such a prolonged and widely spread bodily infection (syphilis) should leave undamaged the vital procreative cells. In what way does this outlook relate itself to practical work? I have personally found it a great stimulus to a better realisation of the reasons for preventive action against the great systemic diseases. The constant thought of death rates and fatal disease is in the end rather depressing. It is like a fresh wind from the hills to conceive that we are, in fact, doing far more—that we are laying the foundations of a work which, in the generations still to come, will largely abolish these chronic indispositions that take so much away from the joy of life. It is true that we are still hampered by lack of knowledge in many avenues, and we wait upon research to show us the lines along which we can usefully apply scientific knowledge. What I do impress, however, is that we as field workers must keep ourselves constantly in touch with all scientific enquiry into such great systemic conditions. Only in that way can we

keep our minds living and appreciative of the trend of modern thought. Again, let me lay stress on this fact—that I am not talking eugenic ideals; I am filled with the thoughts of a practical vision; for our prime function is to guide the public in those ways which will deal effectively with the great causes of ill-health, disablement, and unhappiness. The field of thought which is opened up by such a generalisation of the effect of individual diseases is almost limitless, and it is obvious that a great correlation of what is ordinarily known as scientific medicine with accurate eugenic experiment would be needed to prove categorically what has been thrown out as a truly imaginative concept for your consideration. But it is such thoughts as these that make our work really interesting and constitute what, to my mind, is an orderly imagination of profound value in keeping us really alive and vigorous in mental outlook and capacity for change. . . ."—Dr. R. Veitch Clark, *Imagination in Public Health*, *Public Health*, Nov., 1934, p. 62.

Reduction of Maternal and Infant Mortality in Rural Areas^{*}

J. H. MASON KNOX, JR., PH.D., M.D., F.A.P.H.A.

*Chief, Bureau of Child Hygiene, Maryland State Department of Health,
Baltimore, Md.*

APPROXIMATELY 54 per cent of the inhabitants in the registration area of the United States live in the country or in villages and towns of less than 10,000 population. These rural and small-town residents comprise a larger proportion of native born Americans, white and colored, than is found in the cities. The infusion of young life entering the large centers of population each year comes in large part from these less congested areas. It is important, therefore, that measures intended to promote public health, to diminish illness and death, should at least be equally effective in both rural and urban areas.

The difficulties of carrying out public health procedures in the more sparsely settled parts of the country may be an explanation but not an adequate excuse for the greater protection afforded residents of cities.

MATERNAL HYGIENE

It is not the purpose of this paper to discuss in detail the causes of the high maternal mortality rates in this country. This has been done repeatedly by experienced obstetricians and public health officials. The defects of the present *laissez-faire* procedures have

been thoroughly exposed and the need of more thorough obstetrical training in the medical schools emphasized. Suffice it to say that each year approximately 16,000 comparatively young women die from puerperal conditions producing a maternal mortality of 7 per 1,000 live births.¹ This rate for the whole country has remained at about the same figure for a number of years. Two-thirds of these deaths are from sepsis and toxemia, conditions which are generally preventable. It is with no feeling of national pride that one records that when a Scandinavian woman comes to this country she doubles her danger of succumbing in becoming a mother.²

As is generally known, the figures of the Bureau of the Census indicate that the maternal death rates in rural areas are considerably lower than those in the cities, 6.2 vs. 7.8 per 1,000 live births in 1929.³ This difference in rate however is apparent rather than real and would disappear if the deaths of women, residents in the country and small towns, who come to city hospitals for delivery, were credited to their place of residence. Thus, according to the survey of maternal deaths made recently by the Children's Bureau in 15 representative states, 28 per cent of the women dying in city hospitals from puerperal causes⁴ were non-residents coming largely from rural areas and small towns. Non-resident maternal

^{*} Read before the Child Hygiene Section of the American Public Health Association at the Sixty-third Annual Meeting in Pasadena, Calif., September 4, 1934.

deaths in Baltimore, for example, increased the maternal death rate in the city from 5.9 to 6.8 per 1,000 live births. Last year 23 per cent of the puerperal deaths in Baltimore occurred among residents of the counties of Maryland outside of the city. A study of the maternal deaths in Maryland, exclusive of Baltimore, a few years ago, disclosed conditions which probably are equally true of much of rural America.⁵

As usual, 60 per cent of the mortality was due to sepsis and toxemia. Eighty-two per cent of these women were attended by physicians alone and but 10 per cent by midwives alone. Eighty-nine per cent of the women were married and 66 per cent had older children. Only 8 per cent received anything like adequate prenatal care, and 56 per cent had had no prenatal care whatever. Twenty-seven per cent of the total deaths occurred among women whose pregnancy was interrupted before the 7th month and who had not been under the care of a physician.

A tragic feature of this study was the large number of women who did not consult a physician until serious complications had intervened, usually too late for relief even in the most experienced hands. Surely such conditions which are not exceptional in rural America call for prompt attention and relief. Moreover, it is understood that the neonatal deaths occurring in the 1st month of life, comprising about one-half of the deaths in the 1st year, as well as the stillbirths, can be radically reduced only through more general and adequate prenatal, natal, and post-natal care of the mother.

INFANT MORTALITY

When we turn to a brief consideration of infant mortality in this country we have reason for greater satisfaction. A third of a century ago it is probable that 1 of every 6 infants born alive died in its 1st year. Sir John Simon

of England has asserted that a high infant mortality rate almost necessarily denotes a prevalence of those causes and conditions which in the long run determine a degeneration of race and are an indication of the existence of evil conditions in the homes of the people. Sir Arthur Newsholme has called the infant mortality rate the most sensitive index we possess of social welfare. A high infant death rate means the sacrifice not of the unfit, but of the unfortunate infants, those deprived of proper care.

In the volume on Infant Mortality published this year by the Bureau of the Census it is recorded that in 1930 out of 2,204,000 live births in the birth registration area in continental United States, comprising 94.7 of the total population, there were only 142,000 infant deaths under 1 year, giving an infant mortality rate of 64.6.⁶

The improvement can be seen best in a comparison of the rates in the original birth registration area from 1915 to 1930, inclusive. In 1915 there were nearly 76,000 infant deaths with a rate of 99.6 per 1,000 live births, whereas, in 1930 in the same area, in which the population had increased more than 7,000,000, there were but 43,000 infant deaths with a rate of 62.1 per 1,000 live births. While there has been a continuous reduction in the infant mortality rates during the last 20 years, in both urban and rural areas, the lowering of the rates in the cities has been the more marked.

The infant mortality rate in 1915 was 103.1 in the cities and 93 in the rural sections. The city rate gradually approached the rural rate and since 1925 it has been consistently lower, being 61.2 in 1930 versus a rural rate of 64.⁷

The more rapid reduction of infant deaths in the cities is due largely to the decrease in deaths from diarrhea and enteritis, the mortality rate from these diseases in the cities in 1917 being 23.9

and 6.8 in 1930. In the same period the rural infant deaths from the same causes decreased from 16.1 to 8.4 per 1,000 live births.⁸ This reduction of diarrheal deaths among infants in the large cities is illustrated in a comparison of Baltimore with the rest of the state consisting for the most part of a rural population. There were, in 1933, but 62 deaths from gastroenteritis in infants under 1 year in Baltimore, while in the counties outside of Baltimore, with an approximately equal population, there were 171 infant deaths from these disorders.

This experience is true of other large cities as compared to surrounding country areas. It indicates that the kind of care which keeps a baby well is not equally available in the rural areas and that disadvantages of crowded living conditions are compensated for by better environmental sanitation.

INFANT HYGIENE

Perhaps the most important factors which favor the well-being of the city infant are:

1. Pasteurized clean milk
2. Available infant welfare stations to which mothers of limited means can bring their infants for examination and advice from skilled physicians
3. Home visits by nurses to instruct mothers in the care of their babies
4. Sanitary disposal of waste and a reduction in the number of house flies

This kind of assistance is not so generally provided for the indigent rural mother, which explains in part why she loses a larger proportion of her babies than does the city mother of the same economic status.

When one seeks for a means for overcoming this disparity between the underprivileged infant in the congested districts in the city and the baby of the poor farmer living in the wide-open spaces, it may be profitable to recall the history of the maternal and child hygiene movement in this country.

LAY INITIATIVE RESPONSIBLE FOR THE MATERNAL AND CHILD HYGIENE MOVEMENT

The movement began in the large cities. It was due in a marked degree to the interest and vision of lay groups of interested, socially minded men and women, who became aroused by the suffering and loss incident to the excessive mortality among mothers and infants and took practical steps to improve conditions. Local volunteer organizations expanded into state and national associations which were tremendously influential in awakening public sentiment.

These pioneer activities were often directed by physicians whose experience and knowledge supplied the necessary medical background. The medical profession as a whole, however, was not particularly concerned. Influenced by an aroused public opinion, city boards of health generally followed the paths opened by the volunteer organizations and later depended upon lay support for help in the enactment of milk ordinances and of other measures which have furthered child hygiene.

ACCEPTANCE OF RESPONSIBILITY BY LOCAL, STATE AND FEDERAL DEPART- MENTS OF HEALTH

State departments of health gradually followed the lead of the city boards of health in this field. A great amount of valuable work resulted. Perhaps this very expansion of official activity has rendered it less evident to the influential citizens of rural communities that they have a personal responsibility to help prevent unnecessary deaths among women and children in their neighborhood. To them this seems to be the job of the local health officer and the public health nurse.

Certainly progress at present made in the field of maternal and infant hygiene in the cities would not have taken place had the sole responsibility been

assumed by the professional workers. But a fraction of our rural districts is served by trained whole-time health officers and nurses. Only those with experience in rural work know how difficult it is for a health officer, with 1 or 2 nurses, to carry on adequate maternal and infant hygiene work, in addition to his many other duties, in a scattered population in a large territory without the help and coöperation of interested residents who know and care.

DEVELOPMENT OF PUBLIC SENTIMENT ESSENTIAL TO SUCCESS

One of the important functions of a health officer, who is determined to lower the maternal and infant mortality rates in a rural area, is to develop active and efficient lay support of his undertakings. His personality and his ability to interest the public in his child health program may determine his success or failure in this field. This matter of organizing groups of influential citizens to further a community program in behalf of mothers and infants should be given more emphasis in our schools of public health in addition to the many technical and scientific subjects the embryo health officer is expected to master.

ORGANIZATION OF INTERESTED LAY GROUPS

Experience has repeatedly shown that even in sparsely settled communities which may seem indifferent to high mortality rates among mothers and infants there are always some persons, men and women, who can be interested and organized into a supporting group to sponsor better prenatal, natal, and infant care. Through such a group or committee, lay assistance may be furnished at a clinic, and transportation for certain cases provided. What is more important, through such groups there can be developed a sense of community responsibility for the health of women who are not able to care ade-

quately for themselves or their children. A volunteer organization of this kind grows in influence by the evident justice of the cause it sponsors. Its activities often result in securing additional assistance from public sources toward making environmental conditions more favorable for children.

MEDICAL PROFESSION AS ADVISORY AIDS

Naturally a community looks to its physicians to advise it in matters of health. Certainly individual doctors have played a leading part in the formation of child health organizations in the cities. This is true also in the planning of child health committees in rural areas. It must be remembered, however, that many physicians are rugged individualists, who devote all their time, often for little or no remuneration, to caring for patients who consult them. The sum total of the service they render is incalculable but it reaches a limited group and often does not have a large part in a community-wide plan intended to reach *all* mothers who are in need.

On another occasion the writer has stressed the importance of giving more emphasis in the curricula of our medical schools to the responsibility—not only to his own patients but to the community in which he has cast his lot—which devolves upon a physician by reason of the very knowledge he possesses.⁹ The most meticulous care by a physician of the women and children who consult him may not appreciably lower the morbidity and mortality rates in a whole community. These are largely determined by the lack of care of those who are too poor or too indifferent to call a physician promptly for illness, still less to seek his services in order to keep well.

NEED FOR PREVENTIVE AND CURATIVE SERVICES

The great need in rural America today

is that there be set up in every community some generally accepted plan which will make available both preventive and curative services for those who are not able to provide for themselves. Such a plan will take form when a group of responsible citizens organize for this purpose. It is, of course, desirable that the local health officer, if there is one, sponsor and direct such a movement. The lay public is ready for such action. The education of the laity in maternal and child hygiene is being actively promoted by state and city departments of health and national and state medical societies. Physicians giving professional services in a community-wide plan of maternal and child hygiene should receive fair remuneration.

SPECIFIC PROBLEMS INDICATED

Thus far we have discussed in general terms the present needs of mothers and infants in rural America. It is understood that each section of the country has special problems which must be met by specific measures. The variations in the maternal and infant mortality rates among the several states are sufficient proof of this assertion. In 1929 there were 6 states having a maternal mortality rate of 9, and 2 with a rate of less than 5, per 1,000 live births; in 1930 the infant mortality rates among the states ranged from 49 to 145.

SURVEY OF EXISTING CONDITIONS PRELIMINARY TO ACTION

Any adverse conditions existing in a community should be carefully studied by the proposed local child health committees under the guidance of the health officers and physicians, and appropriate remedies should be applied.

MIDWIVES

I am suggesting a few of the outstanding problems which must be faced in some rural communities in formu-

lating a child health program. Thus, in many rural areas in the South there is the midwives' problem. Steady progress is being made in eliminating the unfit midwives and in instructing those who practise. Even the better midwife, however, has definite limitations. She cannot examine her patient, give her prenatal care, or deliver her if she presents abnormal symptoms. Among the patients employing midwives, the prenatal clinics established by a number of local departments of health have proved of inestimable value. In these clinics the midwife's cases are examined and advised and if unfavorable conditions are found the expectant mothers are referred to physicians or hospitals.

DYSENTERY

In the South too, there are many rural areas in which dysentery is endemic and is the principal cause of a high infant mortality. Carefully controlled studies of this disease have been made recently in West Virginia by Dr. George M. Lyon of Huntington.¹⁰ He finds that from 15 to 80 per cent of all children of 5 years, including those of well-to-do parents, have had dysentery. The milk and water supplies are excellent and do not seem to be involved.

In the territories studied, including several counties in West Virginia, Dr. Lyon shows that the transmission of the disease may usually be attributed to the proximity of the infant to an active case of dysentery and to the unsanitary disposal of sewage, with flies as the most frequent carriers of the infecting agent. Poverty, unhygienic surroundings, and warm moist summer heat are favoring conditions. The importance of carriers in the dissemination of dysentery has been emphasized by McGinnes from studies in Henrico County, Va.¹¹

In situations of this sort, it is difficult for health officers to accomplish results unless they are backed by in-

telligently informed public opinion and have the support of lay organizations that are determined to remove the proven dangers to infant life.

EXCESSIVELY HIGH MORBIDITY AND MORTALITY RATES AMONG THE NEGROES

In the South too, our mortality statistics are affected unfavorably by a large negro population in which the morbidity and mortality rates are nearly double those of the whites. It has been repeatedly shown that these high rates are not necessary, that colored mothers and infants can be saved by the same methods that have proved effective among the whites, *i.e.*, that there is no demonstrated physical inferiority in the negro. He lives at present with lower moral and sanitary standards. There is reason to believe that if conditions were reversed the white mortality would be that of the negro today and the death rate of the negro approximately that of the white. The majority of the negroes live in country districts. Their condition has been improved in proportion as the leaders among them have learned to understand the steps by which the whites have mounted to higher levels of personal and public hygiene, and have been able to persuade an increasing number of their own race to follow.

There is one county in Maryland in which the negro infant mortality rate was much lower last year than that of the white. This was due in no small part to the coöperation the enthusiastic, intelligent, colored public health nurse in that county secured in the many households she visited.

MATERNAL AND INFANT CARE IN ISOLATED COMMUNITIES

That the lives of mothers and children in a so-called backward country area can be saved by those who know and are willing to lead, is nowhere better demonstrated than by the work of the

nurses of the Frontier Nursing Service in the Appalachian Mountains under the inspiring direction of Mrs. Mary Breckinridge. These mountain women have been helped to have their babies safely in a terrain without roads and amid primitive conditions. Similar organized effort would save women and infants now being lost in many rural areas much less difficult to traverse.

CLINICS IN RURAL DISTRICTS

Our experience in rural Maryland indicates that prenatal or child health consultations supported by a coöperative sentiment are effective means of reducing maternal and infant death rates. A special advantage of these clinics has been the discovery and successful treatment of a number of women with contracted pelves, with syphilis, or with threatened eclampsia. It is a reflection upon the social conscience of any community when complications of this sort are not discovered until it is too late to make the needed assistance available. When these clinics are established, a considerable proportion of the patients go to physicians of their choice for the treatment advised at the consultation and, moreover, certain families of moderate means seeing the advantage of the services at the consultations, seek similar services from their own doctors and are willing to pay for them.

The point stressed in this paper is not the necessity for any particular form of clinic or health center, although in many instances the prenatal and child health consultations have met the most outstanding needs. It is rather that, having ascertained the reasons for the unnecessary deaths of mothers and infants, each community through the leadership of informed groups of citizens should see to it that the assistance required to combat these mortalities is provided.

COMMUNITY PHYSICIANS

In some parts of the country where

families are widely separated, the employment of community physicians, who, in addition to their private practice, are expected to give preventive and curative treatment to those of limited resources, may be the best method of meeting the situation. In other communities a system of health insurance covering the care of the mother and infant may be an effective means of securing medical supervision.

In any case, measures which have proved successful in reducing infant deaths are well known and are not beyond the resources of any community. It does require vision and interest on the part of those who lead in community affairs. A local health officer with qualities of leadership can greatly further his cause if he takes time to develop this kind of support.

There is no adequate reason anywhere in this nation for losing more than 2 women in every 1,000 deliveries, or more than 50 infants under 1 year, in 1,000 live births. A larger loss of mothers and infants is preventable and discreditable. It means that the given community does not sufficiently care. An aroused public sentiment could make it difficult for any woman to approach child bearing without previous medical supervision, provided that this service is made available by the community as her right if she cannot furnish it for herself.

A CHILDREN'S CODE

There has recently come to the writer's attention a children's code promulgated on April 6, 1934, in that progressive sister republic in South America, Uruguay.¹² This code seeks to correlate the various regulations intended to protect the life and welfare of the child from the prenatal period through adolescence. The enforcement of the code is under the direction of a control council and of provincial and local committees. The council shall

establish the general principles which shall govern the protection of children. These regulations shall be followed by various coöperating committees. The code includes in its provisions the protection of the expectant mother and the new-born infant.

Prenatal protection comprises eugenics, prenuptial examination, care of the pregnant women, including the lying-in and postnatal periods, and the teaching of prenatal care.

Infant protection comprises child health centers, infants' homes, methods of reducing infant morbidity and mortality, mothers' pensions, and the prevention of abuse of children.

The general regulations determined upon by the central council are to be carried out throughout the country by local committees composed of lay and medical members. One may well ask, if in Uruguay, why not in the United States of North America!

SUMMARY AND CONCLUSION

It is the object of the paper to point out that the maternal and infant mortality rates are unduly and unnecessarily high in many rural communities in this country.

These deaths can be decreased when leading citizens are informed and organize to promote corrective measures such as environmental sanitation or the provision of medical and nursing supervision for the indigent as may be needed in their own neighborhoods. In these activities such a committee should be guided by the best professional advice available.

A local health officer can greatly increase the efficiency of his program of maternity and child hygiene if he is able to arouse the active and organized support of those citizens accustomed to lead a community enterprise.

New York Academy Passes on Vitamin "D" Milk

AT the request of the New York City Department of Health, the New York Academy of Medicine, through its Committee on Public Health Relations, made a study relative to the desirability of making energized milk generally available in New York.

A sub-committee consisting of:

Herbert B. Wilcox, *Chairman*
 Paul Brooks
 J. M. Lewis
 Edgar Mayer
 Earle B. Phelps
 E. H. L. Corwin, *Secretary*

prepared the report which was adopted by the Committee on Public Health Relations. This report discusses the reasons for Vitamin D milk, the three methods of producing it (Zucker process, feeding of cows with irradiated commercial yeast or ergosterol and direct irradiation of the milk itself), and the physical, biological, and clinical tests involved and the administrative problem.

The committee is of the following opinions:

1. Since the Zucker cod liver oil concentrate is practically a sterile product when it leaves the manufacturer, the amount added to the milk is small and the procedure involved in

adding the concentrate to the milk by the distributor is one not requiring contact with human hands, the hazard of contaminating the milk is so slight as to be negligible, providing the milk is pasteurized after the addition of the concentrate.

2. From the standpoint of medicine and health, there is no valid objection to permitting the addition of Vitamin D to milk by any one of the recognized methods under properly controlled conditions.

3. Vitamin D milk, produced by any one of the three methods, should be allowed to be sold, provided the containers carry a label to the effect that it is Vitamin D milk and indicating the process used.

4. For the present at least it is desirable that the label merely states the source of Vitamin D, the health department to decide what it considers a normal protective dose and in its license provisions demand proof from time to time that the milk produced under the license contains the stated dosage.

5. Since the production of Vitamin D is still experimental, the basis for establishing minimum standards for Vitamin D content are unsettled and laboratory service for the purpose of making assays is limited, the official health agencies in the State and City of New York would be acting wisely if they deferred, for the present, the enactment of detailed and specific requirements beyond those necessary to assure a product of safe sanitary quality.—Committee on Public Health Relations Report on Vitamin D Milk. *Bulletin of The New York Academy of Medicine*, August, 1934.

The Ninth Pan-American Sanitary Conference

KENDALL EMERSON, M.D.

Executive Secretary, American Public Health Association, New York, N. Y.

THE Ninth Pan-American Sanitary Conference was held in Buenos Aires from November 12 to 22, 1934. It had the distinction of being the first Conference at which delegates were present from all of the twenty-one Republics of America. Among the important topics discussed were suggestions for revision of the Pan-American Sanitary Code, which has been signed by all but one of the Republics and which deals with the international reporting of certain epidemic diseases and quarantine regulations for air and water navigation; and adoption or approval of the International Sanitary Convention for Aerial Navigation, proposed at Paris on April 12, 1933, and already adopted by a number of European governments.

After considerable debate it was finally agreed that the Pan-American Sanitary Code should not at this time be subjected to formal amendment, but that certain interpretive clauses should be formulated by the present Conference and recommended to the several governments as the sense in which the articles of the Code to which they refer should be applied in actual practice, specifically in cases where reservations or difficulties in the working Code provisions had been encountered. These interpretations concerned themselves with: conditions under which notification of the existence of epidemic diseases should be mandatory; approval of

the use by airships of the entry of sanitary information in the log book in lieu of a bill of health; a certain liberalizing of the deratization regulations in vessels built according to approved international rat-proof specifications, or supplied with adequate certificates of deratization.

The International Sanitary Convention for Aerial Navigation was read by the Delegates and its provisions were considered with much care. The Conference voted its agreement with the fundamental doctrines of the Convention and the delegates will recommend to their respective governments adherence to its regulations and its formal ratification.

To expedite consideration of the thirty-two articles on the agenda of the Conference, six Committees were appointed as follows: Committee on Resolutions; Committee on the Pan-American Sanitary Code and the International Sanitary Convention on Aerial Navigation; Committee on Tropical Diseases; Committee on Yellow Fever; Committee on Venereal Diseases; and a Committee on Plague. These committees met and after much discussion formulated certain resolutions regarding the topics assigned for their consideration. These resolutions were subsequently laid before the plenary sessions of the Conference and most of them were adopted with or without modification. They are embodied in the

"Acta Final" of the Conference and will serve as a valuable guide in future Pan-American Sanitary relationships.

The work of the Conference embraced a wide field of public health interest. Its deliberations may be divided into two broad categories: international problems involving the spread of epidemic disease from country to country through commerce and intercommunication; internal questions of public health administration such as municipal and rural sanitation, centralized or provincial authority, hospital and dispensary provision, protection of the milk supply, nutrition, maternal and infant welfare, preschool and school hygiene, tuberculosis, venereal disease and popular health education. At first thought discussion at an international gathering of health problems largely local in character might seem out of place. But just as in any community the standard of health is no higher than the average health of the families of which it is composed, so in the Pan-American family of nations health standards can only be truly gauged by those prevailing in each of the countries included. The Sanitary Conference provides an admirable channel for comparison, through formal report and through personal contact, of the various methods employed in the different countries and their indices of efficiency in the hands of the several administrative officers. It must be remembered that with the vast distances involved such comparisons can be of infrequent occurrence when contrasted with the easy communication possible between State Health Departments in North America.

A full report of the proceedings of the Conference will be issued shortly by the Pan-American Sanitary Bureau in Washington. Reference will be made here to but a few of the subjects discussed. In the administration of public health there is a very clear recognition of the evils involved in the effect

upon it of abrupt political changes. Certain of the Latin American countries are more fortunate than we in our State Health Departments since they appear to have a secretariat of health which carries on despite changes at the top, political preferment perhaps not penetrating as deeply as with us.

There is recognition of the value of the public health nurse and also of the social worker. As yet, however, very little provision is made for such activities in most of our neighboring countries to the south. It would be difficult to meet the expense of maintaining these services from public funds and at the present time adequate training schools for nurses exist to a very limited extent. A similar difficulty confronts most of the countries in the matter of expert public health personnel, there being limited opportunity offered for the technical training of public health executives.

Plague continues to be a major problem of international sanitation. Its existence as an epizootic among inland rodents of certain countries, including the United States, is a probable source of re-infection of port rats adding to the difficulty of keeping ports clean. Both Ecuador and Peru were congratulated on the success with which they were handling their plague problems. It is gratifying to record that the campaign in these two countries is under the direction of an able representative of the Pan-American Sanitary Bureau delegated for this work by the United States Public Health Service. A very efficient system of rat poisoning through the use of food packets containing arsenic has been installed and careful laboratory examinations as well as the reduction of human cases demonstrate the happy results thereby attained.

An interesting discussion arose as to the possibility of the introduction of plague bacilli to American ports through infected fleas in jute bags brought from

Oriental districts. The international Public Health Office of Paris does not feel that the case is proved, while outbreaks of plague in certain places in Peru following the unloading of jute bags containing living fleas on arrival were offered as supporting evidence. So far no plague infected fleas have been found in these bags, but it has been shown by other observers that unfed infected fleas may retain for several months the power to transmit the disease.

The Conference recommended to all the countries represented unremitting efforts toward the extermination of all plague foci and all plague carriers to the end that this grave menace to the public health might ultimately be completely eliminated as a factor in international commerce and communication.

The session on yellow fever was of special interest, evidence in the form of reports of positive serum reactions (mouse-protection test) indicating that the disease exists today in the interior of several South American countries, in one of which it is rather widely disseminated. The same is true to an even greater extent of the countries of tropical Africa.

The fact was also brought out that deaths from yellow fever occurred in regions where no *Stegomyia* mosquitoes or larvae could be found, leading to the belief that some other carrier might be responsible.

Delegates from all the countries reported that malaria continues to be among the most costly of endemic diseases and one that is most difficult to combat. It was recommended to continue the investigations going on at several places or even to create new centers for study of this serious public health problem. It was further recommended that the results of such studies be forwarded to all the countries in the Pan-American Sanitary Conference either directly or through the Sanitary Bureau

and that the various species of anophelines which carry the disease be studied and special methods recommended for the eradication of each. Further studies are also needed in the use of quinine and other drugs as prophylaxes against the development of the plasmodia.

It was recognized that at the present time there is a persistent epidemic of typhus exanthematica in Chile and that country was encouraged to make every effort to bring it under control. At the same time a vote of applause was given the Chilean Health Authorities for their success in preventing the spread of the disease to other countries.

There was considerable discussion of the different strains of typhus fever virus, especially of flea-borne and louse-borne types, with the possibility of these types being reciprocally "revertible." It was agreed that it was not necessary to report flea-borne (endemic) typhus to the Pan-American Sanitary Bureau by telegraph or cable, but that the "epidemic" form of the disease should be so reported.

The increase of undulant fever was noted in reports from several countries and a long resolution was adopted recommending the intensive study, bacteriologically and epidemiologically, of this disease. There are a number of questions still requiring much investigation, such as the relationship of the disease in man and animals, its intercommunicability and the methods whereby this may take place, as for example, through milk and milk products, the value of vaccination and the danger of using living germs for this purpose, the disease considered as a problem in industrial hygiene, and other phases of this complicated and increasing menace to public health.

The discussion of smallpox as an international health problem was gratifyingly brief, indicating that control of this disease is on a relatively satisfactory

level. Brazil presented a report advocating the use of the single vaccination as giving as effective results as the more common practice of revaccination, at intervals or during epidemics, of those already successfully inoculated. The suggestion was referred to the various countries participating for further study, the Conference not expressing an opinion on the report.

Tuberculosis is recognized as one of the major problems in all the countries represented. While the death rates from this disease did not appear to be alarmingly high in certain countries, skepticism was freely expressed by the delegates as to the accuracy of mortality records. In the Argentine itself there are about five deaths annually for each hospital bed available and sanatorium construction is recognized as the first need in better organization of the anti-tuberculosis campaign. Voluntary tuberculosis associations exist but command relatively little public support.

BCG was discussed at length and it was found that its use was prevalent in a number of the South American countries. The delegation from the United States set forth the conservative attitude which had been adopted in North America pending the outcome of more carefully controlled experiments both as to its harmlessness and its effectiveness as a preventive medical measure. The Conference voted that, in spite of the encouraging results which American experience seemed to have indicated, it appeared wise to reserve a final expression of opinion regarding the general use of the procedure and to recommend its employment only in those cases where vaccination with BCG appeared to offer the only, or at least the most probable, method of protection for an individual infant.

Venereal disease is considered one of the major menaces to public health and all of the delegates expressed the

opinion that greatly added facilities were urgently needed to combat this danger. Educational means were advocated and the provision of more adequate dispensary service together with increase of the free distribution of neosalvarsan.

A resolution of gratitude to the Rockefeller Foundation was passed for its work in the eradication of ankylostomiasis and all countries were urged to continue unremittingly their attack on this disabling disease.

It was recognized by the Conference that while the sanitation of cities, especially those ports involved in international commerce, had progressed to a striking degree during the past thirty years, rural sanitation had by no means kept pace with this progress in most of the countries participating. A resolution was passed stressing the importance of more attention to this very essential phase of public health work and encouraging all the countries to increase their facilities for its expansion.

Maternal and infant welfare projects were reported from several countries and the children's code originated and practised by Uruguay was recommended for favorable consideration by the delegates. Preschool and school hygiene were admitted to be still in an embryonic state and their importance to the public health was clearly pointed out. It was resolved to further the interchange of experiences in these branches of preventive medicine, with especial reference to the desirability of periodic health examinations, the correction of remediable defects and the keeping of adequate records of the health of school children.

Nutrition, safeguarding food supplies, the international traffic in drugs and alcohol, and especially the necessity for greatly increased popular health education were among the many other topics discussed.

As has been mentioned, the outstanding feature of the Ninth Pan-American Sanitary Conference was the fact that all the Republics of the two continents were represented by officially appointed delegates. In addition, the reports of public health progress made in the several countries were most carefully prepared and will be most valuable in documenting present practice in preventive medicine. Discussion was abundant, radical disagreements rare, and

there was a gratifying accord on questions of fundamental significance to the underlying principles of public health. A number of topics were left open for further discussion and referred to the next Pan-American Conference for its consideration. Aside from its scientific value, the meeting was notable for the fine spirit of friendliness which prevailed and as an effective opportunity for the promotion of international amity and understanding.

Negro Housing Projects

COL. H. B. Hackett, Director of the PWA Housing Division, lists the following Negro housing projects as now under consideration in his department:

Atlanta, Georgia: University Housing Project, to rehouse 617 families in 2-story row houses and 3-story apartments. Project will contain 2,457 rooms, be built on fraction of 800,000 sq. ft. of land, cost (estimate) \$1,900,000.

Indianapolis, Indiana: Indianapolis Community Housing, 1,044 dwelling units containing 3,190 rooms in 2-story

row houses and 3-story apartments. To be built on 940,000 sq. ft. area, to cost (estimate) \$3,000,000.

Montgomery, Alabama: Thurman Street Project, to rehouse 161 families in 1- and 2-story row houses, each with separate yard and porch. Land area to be used, 300,000 sq. ft., cost to be (estimate) \$315,000.

Similar projects are under consideration in Detroit, Cleveland, and Washington, for which complete information is not yet available. Rentals have yet to be determined for each project.—*Public Housing Progress*, Nov. 15, 1934.

LOOKING AHEAD IN PUBLIC HEALTH

AT this time of year many health officers have already planned their budgets and activities for the ensuing year based entirely upon consideration of local problems and resources. Little consideration by health workers has, however, been given to any national program to improve or extend the public health facilities generally of local, state, and federal health agencies. The effects of the depression upon health work which have been frequently reviewed through the columns of the *Journal*, have been, in essence, to reduce personnel and budgets for state and local health services about 20 per cent on the average. The federal support of activities which aided state and local areas has been reduced an even greater amount. To counteract this in part, a number of emergency relief projects have been provided in the public health field dealing largely with environmental sanitation. More recently an allocation of \$1,000,000 from relief funds to the U. S. Public Health Service for aid to state and local health departments has served to relieve the local situation somewhat. But something more than these sporadic and temporary measures is needed to provide effective, well planned and conscientiously executed full-time health supervision.

For a number of years the Association, through the *Journal* and otherwise, has urged broad gauge consideration of public health by the federal government and the development of plans whereby federal influence and resources could be effectively utilized to stimulate further support and aid of local and state health departments.

The President has recently appointed a Committee on Economic Security. Obviously, public health service along the lines now generally accepted and known to be effective, if extended to reach a large majority of the population, would make a real contribution toward economic security, through minimizing the tremendous annual loss from preventable diseases which now amounts to hundreds of millions of dollars.

The President's interest in public health is well known. That he has a sound conception of the fundamental responsibility of government for the organization and support of health services is evident from the report of the New York State Health Commission which he appointed and sponsored.

We believe that this is a most opportune time for health workers to make known their problems and to state clearly the need for federal leadership in health matters and the degree to which the population suffers both economic loss and physical impairment because of diseases demonstrated to be preventable.

Through these columns we have repeatedly urged members to acquaint their representatives in Congress with the importance of public health, and the necessity of federal action in support of health work. We again suggest that you use every means at your disposal to interest your representatives in Congress in the passage of constructive measures and provision for more adequate support for federal health agencies.

More than this, we suggest you write to Miss Frances Perkins as Chairman of the Cabinet Committee on Economic Security, or to Mr. Henry Morgenthau, Jr., as Secretary of the Treasury, or to President Roosevelt, telling of your local health needs which are as yet unmet or which have been curtailed through budgetary cuts, and pointing out the desirability of federal aid and leadership and the need of increased appropriations for the conduct of health services of the federal government, particularly of those of the U. S. Public Health Service and the Children's Bureau to permit them to function effectively in their appointed fields.

You, as health workers, should voice public opinion in health matters and cannot expect your government to provide service for which there is no expressed demand. It follows therefore that unless you are willing, personally and through locally important people, to use every effort to influence federal activities at this time, you must not be dissatisfied with the crumbs of consideration which the work has received in the last few years.

MORE TRUTH IN VITAL STATISTICS

THE great development of hospital facilities in cities during recent years has brought with it a misleading inflation of birth and death rates in certain urban areas, and fallacious reduction of the corresponding rural rates. On the other hand, sanatoria have tended to transfer deaths from cities to rural areas.

As an extreme example of the serious distortion which may be produced by the factor of nonresidence: in New York State, the 1931 birth rate for the upstate urban area, as ordinarily recorded, was 18.1 per 1,000 population, which is 50 per cent higher than the recorded rate for the rural areas. But when correction is made for nonresidence, the urban and rural rates are found to be identical, *viz.*, 16.1.* Again, the uncorrected death rate was slightly higher for urban than for rural areas; but after residence correction this relation was reversed: 11.6 for urban, as against 13.4 for rural. More extreme distortions may be cited in the death rates of such hospital centers as Rochester, Minn., and Ann Arbor, Mich. The effect of such bias has been to make some tables a little worse than useless.

* Report of Committee on Residence Correction, Vital Statistics Section, A.P.H.A., presented at the Pasadena meeting, September 3, 1934. To be published in the 1934-5 Year Book.

There have been sporadic attempts to correct this situation by the publication of residence corrected tables in federal and in certain state reports, but too often the correction has been incomplete, or has applied only to a few tables, such as deaths from all causes, or from a few selected causes.

In the light of the growing importance of this problem it is highly gratifying to be able to report two important recent developments. One is that the Division of Vital Statistics of the U. S. Bureau of the Census has expressed the intention of publishing its birth and death statistics on a residence corrected basis beginning with the 1935 volume.

The second development is that the 1932 *Vital Statistics Report* of the New York State Health Department carries, for the first time, a relatively complete set of tables for all administrative divisions of the state, corrected by intra-state transfer of nonresident births and deaths. Earlier reports had published special tables with residence correction, but this, so far as is known, is the first American report in which one can seek information concerning practically any intra-state vital statistics of importance, with the assurance that the data are not seriously biased by the residence factor. The Department of Health of New York State and the Director of its Vital Statistics Division are to be congratulated upon this notable contribution.

CHARLES PORTER, HONORARY MEMBER, SOCIETY OF MEDICAL OFFICERS OF HEALTH

AT the Annual General Meeting of the Society of Medical Officers of Health of England, Dr. Charles Porter, Honorary Member of our Association, the Editor of *Public Health*, and the author of the letter to our *Journal* from England, retired as President.

A unanimous vote of thanks to the retiring President was passed, and Professor W. W. Jameson said that "of all the Presidents of recent years, not one of them deserved the office of President of the Society more than Dr. Porter, who, in all the years of his connection with it, had thrown himself heart and soul into the work and organization of the Society. During his year of office he had done a great deal to enhance the prestige of the Society; he had attended all the meetings and gatherings," and had spoken in behalf of the Society on many occasions. While regretting the loss of his services as President, it was realized that he would now be at liberty again to devote his energies more fully to his duties as Editor of *Public Health*.

Dr. Porter is succeeded by Dr. R. Veitch Clark, Medical Officer of Health of Manchester. He has given distinguished service and has had the exceptional honor of occupying the Presidential chair of two Branches of the Society, the Home Counties and the North-Western. At his installation, he gave a most thoughtful and stimulating address on "Imagination in Public Health."

CHARLES V. CHAPIN, HONORARY FELLOW, SOCIETY OF MEDICAL OFFICERS OF HEALTH

ONE very pleasing event of the afternoon was the election, to the Honorary Fellowship of the Society, of Dr. Charles V. Chapin, formerly Superintendent of Health and Registrar of the City of Providence, R. I., a position he

had occupied continuously from 1884 till 1932. Though those who moved and supported the enrollment of Dr. Chapin had words to say in support of the proposal, and references to make to the services rendered by him to public health and preventive medicine not exclusively in his own area but throughout the United States and the world at large, actually there was no need for commendatory words. The name of Chapin is known to every Fellow of the Society and to everyone engaged in the health service of this country. He is and always has been regarded as a leader in sanitary science and preventive medicine, and his pronouncements have always been received with respect, and generally regarded as indications as to the line that might safely be taken at once and that inevitably would be taken eventually. It has always been a matter of real pleasure and for congratulation that Chapin was and had been during his working years an ordinary Fellow of the Society. The opportunity of transferring a colleague from the list of ordinary Fellows to the roll of Honorary Fellows presents itself so rarely that the feeling of gratification naturally experienced was very greatly enhanced in the case of Dr. Chapin. Indeed, the only possible reason for regret was that so long a period had been allowed to elapse before the elevation had taken place. There was this also, that to a certain extent in entering the name of Dr. Chapin a link in the chain binding the United States and ourselves, missing since the death of Dr. Welch, had been replaced."—*Public Health*, Nov., 1934, pages 64-65.

SOUTHERN BRANCH OF THE A.P.H.A.

THE third annual meeting of the Southern Branch was held at San Antonio, Tex., November 13 and 14, conjointly with the Southern Medical Association. The meetings were presided over by Dr. Arthur T. McCormack, Health Officer of Kentucky.

There were some 250 registrations, and a number of visitors from outside of the southern section, many of whom took part in the discussions. At the same time the American Society of Tropical Medicine and the National Malaria Committee met, and some joint sessions were arranged which were full of scientific interest, and especially applicable to those living in the southern part of our country and the countries south of us.

The Southern Branch had a full program which made attendance well worth while even if there had been no conjoint meetings or other papers of much interest in the several societies meeting.

Among the distinguished visitors was Dr. Miguel E. Bustamante, Chief, Bureau of Federal Health in the Mexican States. A letter was received from Dr. Manuel F. Madrazo, Chief of the Department of Public Health, and was read by the President. It contained an invitation to our members to take part in the Post-Convention trip to the City of Mexico. Unfortunately only a limited number could do so.

It may be noted with satisfaction and pleasure that at every meeting of our Association for some years past our sister Republic to the south, which is a constituent member of our Association, has been represented, and we trust that each year will bring an increasing number of the health officers of that country to meet with us. Dr. Bustamante introduced two health officers from Mexico who were with us, Dr. Manuel B. Marguez Escobedo, Guanajuato; and Dr. Telesforo Chopa, Monterrey.

Altogether, the meeting was most enjoyable and most successful.

MEDICAL AND SCIENTIFIC ENGLISH

AS long as the medical profession contains men capable of producing such articles as that given by Dr. Hurter as his inaugural address¹ before the 95th Session of the Liverpool Medical Institution, it will be to a large degree safe from some of the charges leveled against it, chiefly by editors, and often with good reason. Even those who consider themselves scholars will doubtless be surprised at the wealth of material given in this short address. In commenting upon it, the *Journal of the American Medical Association* quotes the opinion, ascribed to experts, that there are scarcely 100 competent medical writers in our country today, while others believe that the number is no greater than 10 or 12. Certainly every editor will agree to a greater or less extent with these opinions. Writers do not seem to recognize that careful editors are apt to be prejudiced for or against the contents of an article somewhat by the way in which the writer expresses himself. Perhaps this is in a measure unjust. There are rough diamonds who have not yet learned to use language but, as a rule, we cannot but agree with the statement of Buffon that a man's style is the man himself. Carelessness in expression certainly indicates some lack of an orderly mind and leads one to suspect the value of alleged scientific facts expressed in loose language.

We believe that Dr. Hurter uses the word jargon in its older sense, though he clearly recognizes its descent into slang. In its older senses, it means "the dialect of a special sect or fraternity." "Applied contemptuously to the language of scholars, the terminology of a science or art, etc." (1651). Dr. Hurter recognizes vocabulary jargon and composition or prose jargon. Of the latter he gives an example taken from a lecture by Sir Arthur Quiller Couch, at Cambridge, some 20 years ago, which is classic:

A.D. 1604

To be, or not to be;
that is the question
Whether 'tis nobler
in the mind to suffer
The slings and arrows
of outrageous fortune,
Or to take arms
against a sea of troubles,
And by opposing
end them? To die: to sleep;
No more; and by a sleep
to say we end
The heart-ache, and the
thousand natural shocks
That flesh is heir to,
'tis a Consummation
Devoutly to be wished.

A.D. 1913

To be, or the contrary? Whether the former or the latter be preferable would seem to admit of some difference of opinion; the answer in the present case being of an affirmative or a negative character according as to whether one elects on the one hand to mentally suffer the disfavour of fortune, albeit in an extreme degree, or on the other to boldly envisage adverse conditions in the prospect of eventually bringing them to a conclusion: The condition of sleep is similar to, if not indistinguishable from, that of death; and with the addition of finality the former might be considered identical with the latter; so that in this connection it might be argued with regard to sleep that, could the condition be effected, a termination would be put to the endurance of a multiplicity of inconveniences, not to mention a number of downright evils incidental to our fallen humanity, and thus a consummation achieved of a most gratifying nature.

Dr. Hurter points out the difference in length between Shakespeare's lines and the transcription into jargon, the former having 72 words against 161 for the latter. He holds that circumlocution, as shown in the transcription, is a main feature and one of the vices of Jargon. Shakespeare used concrete words to symbolize abstract ideas by images, whereas Jargon fails completely because "it discards the concrete and relies almost entirely on vague abstract expressions."

Jargon feeds on the pompous display of sonorous polysyllables and vague "wooly" abstract nouns which "are its very life blood."

The lesson for doctors pointed out is that they should write in the active voice and use transitive verbs, for example: "The nurse gave him morphine hypodermically," instead of "He was subjected by the nurse to the administration of a hypodermic injection of morphine." How few editors have escaped torment from the misuse of the words "case" and "instance"! Sir Arthur Quiller Couch said, "The man who writes 'Instances of premature mortality are more frequent in the case of men than in the case of women,' when he means that more men die young than women, sins against the light." In a recent paper the writer found, "These cases contracted their infection at . . ."

Sir James Barrie is quoted as saying "The Man of Science appears to be the only man who has something to say, just now—and the only man who does not know how to say it." It is not clear that doctors were included in this criticism, though there is no doubt that the "taunt is not altogether undeserved by many scientists and doctors even to-day."

An example of the practical value of style comes to mind. One of the most famous physicians of America, noted for his originality and the operations he devised and carried out successfully, wrote what has been called "the first thoroughly comprehensive book on the subject in America." It was well received, but had no extraordinary circulation. About the same time another noted physician wrote on the same subject. The latter was a successful practitioner, not at all original, and we know of no operation that bears his name. He was, however, a master of English and style. His book was translated into French, German, Italian, Spanish, and Chinese, and 60,000 copies were sold.

We have always deplored the cutting of fundamentals from the required studies in colleges and universities. Greek and Latin, for example, may have little direct bearing on surgery or internal medicine, but their study gives an appreciation of culture and assists in the use of language. In the hurry of American life, have we not taken too many short-cuts? English medical writers show a broader culture than American as a rule, and we believe this is due to better fundamental education, and a comparative freedom from the desire to master the practical and money-making arts.

PUBLIC HEALTH EDUCATION*

PUBLIC HEALTH INSTRUCTION

IT must bring to the people only what is established on a sound scientific basis. It must present its facts with the most effective technic, as to selection of content and form, so as to make the essential facts clear and to arouse an effective desire to apply them. And, finally, the program must be so planned as to emphasize those things which are vitally important and to do so at the times and under the conditions where application of the principles in question can most easily and effectively be made.

C.-E. A. WINSLOW

"The Crying Need of the State"—A "Health Survey of the State of New Mexico," sponsored by the New Mexico Tuberculosis Assn., and published by the state, is edited by Carl E. Buck.

Among the recommendations for the State Bureau of Public Health it is good to note the following:

A reasonable appropriation for public health education. At the present time there is no special appropriation for this work and yet public health education is the crying need of the State of New Mexico.

Then there is this:

Two additional persons, one a stenographer at \$1,400 per year and the other an assistant in health education at \$1,500 per year. (\$2,900.)

Proposed also are 3 supervising nurses at \$2,400; 11 county nurses at \$1,800; and 28 sanitary inspectors at \$1,500.

We wish that the report had given some indication of the duties of "an assistant in health education." Lacking that information we are glad that

the health educator rates no lower than the trained sanitary inspector and that as "an additional person" he will have a \$2 a week edge over the stenographer who doubtless will be a commercial college graduate.

Extremes in the Movie Industry—From June, 1933, to June, 1934, some 500,000 people in 60 cities of 15 states saw "Damaged Lives" and the film lecture on syphilis, "Science and Modern Medicine," and 90,000 carefully prepared pamphlets were sold to those who saw the films.

But the irresponsibility of local exhibitors made it necessary to withdraw the A.S.H.A. endorsement of the picture. Some of the local advertising was of a sensational or salacious nature. In at least one city the picture was accompanied by a lecture of objectionable character, and unauthorized pamphlets were sold at a high rate.

The other extreme was the censorship which closed to the picture some 37 per cent of the potential audience, including the states of New York, Pennsylvania, and Ohio.

If the picture is shown anywhere under the supposed auspices of the

* Please address questions, samples of printed matter, criticism of anything which appears herein, etc., to Evart G. Routzahn, 130 East 22d St., New York, N. Y.

American Social Hygiene Association you will help by quickly notifying the association at 50 West 50th St., New York, N. Y.

"Doctors, Dollars and Disease"—This is the title of a series of radio programs on medical economics which will run through Feb. 25, 1935 (with 3 exceptions), on Mondays at 10:30 P.M., E.S.T., over WABC, Columbia network, 60 stations. For a full list of topics write to National Advisory Council on Radio in Education, 60 E. 42d St., New York.

The Advisory Council says:

This series of broadcasts will consider the subject of medical economics, the cost of medical care, the relation between the medical profession and the public, the ways of reconciling the interests of the two groups.

The recent progress of the science of medicine has been little short of miraculous. Physicians as a rule have shown fine professional spirit and have given freely of their time without pay. Yet more than 50 million persons in the United States either do not receive the care which they need, or are heavily burdened by its costs, while many practitioners and agencies for health are under-employed and poorly paid. The barrier is mainly economic. It stands between the doctors and the dentists and the nurses who are able and eager to serve and the patients who are sorely in need of the service. The problem is to bring doctors and dollars and diseases into such helpful and continuous contact with each other that the *practice* of medicine can keep pace with the *science* of medicine. That is the central theme of this series.

The series was arranged by a Public Health Committee of the Advisory Council, with a chairman who is an economist, and five members who are in public health or have been associated with public health interests.

What Education Has Been Done—Brief extracts from annual reports tell us what has been done and sometimes illustrate the meagerness of our tangible, reportable efforts. We hope

to quote from various reports from time to time.

The New Haven (Conn.) Foundation reports:

Educational publicity on the early signs and symptoms of the diseases was carried on in the same manner as in the preceding year. A total of 22,900 pamphlets were distributed in the city and certain sections of the Metropolitan Area. This distribution was supplemented by local newspaper articles and talks to lay and professional organizations. Hospital records for the year 1933 indicated a continued steady decrease in the median period of delay between primary symptoms and hospitalization. It is conceivable that the committee's educational policies may be partly responsible for this. That the median decline from 7.8 to 5.6 months in a period of 4 years has been less rapid than might be expected may be due to the fact that about 47 per cent of all cancer cases hospitalized during this period have been non-residents—many coming from areas outside of the committee's sphere of educational influence.

What Radio Objected To—In November the Columbia Broadcasting System refused to allow syphilis to be mentioned by Dr. Thomas Parran, Jr., who was to have spoken in the "Doctors, Dollars and Disease" series.

The censor objected to these two paragraphs:

Against cancer, no progress has been made. Yet many cancer victims could be completely cured if only the disease were recognized in its early stages. We have made no progress against syphilis, though its end results crowd our jails, our poorhouses, and our insane asylums. Yet there are specific methods of controlling it better known to science than the methods of controlling tuberculosis. We need only to do what we know how to do, in order to wipe out syphilis as a public health problem.

In my philosophy, the greatest need for action is where the greatest saving of life can be made. I consider, then, that our greatest needs in public health are first, the leveling up of present services so that every community may receive the benefits that have long accrued to the leaders; and second, a frontal attack by all communities against maternal mortality and deaths among newborn infants; against dental and faulty nutrition; against tuberculosis, where splendid

gains have been made; against cancer and syphilis, where we have done little or nothing.

The leading newspapers of New York City mentioned the incident, explaining that syphilis was the objectionable word.

Baltimore, Connecticut, and Illinois—In Baltimore, as a rule, broadcasts are sponsored jointly by the City Health Department and the Medical and Chirurgical Faculty of Maryland. The following topics were presented in October and November:

Diphtheria Prevention . . . The Department of Education and the Diphtheria Prevention Campaign . . . Parent-Teacher Associations Believe in Diphtheria Prevention . . . Catholic Schools and the Diphtheria Prevention Campaign . . . What You Should know About Hearing . . . Autumn Chills and Colds . . . Has Your Child Been Protected? . . . The School Lunch . . . Why Fumigation Has Been Abandoned . . . Sensible Safeguards in Communicable Disease Control . . . Carbon Monoxide—The Unseen Foe of Man.

Various staff members of Connecticut Department of Health shared in the broadcasting of the following topics:

Safe Bathing . . . How Did You Sleep Last Night? . . . Is There Protection? Against Venereal Diseases? . . . Adolescence—A Period of Development . . . The Physician and the Public Health Nurse . . . The Laboratory's Part in Disease Outbreaks.

For many months now all broadcasts of Illinois Department of Public Health have been prepared by Dr. C. M. Chamberlain, of Division of Communicable Diseases. Recent topics have been as follows:

New Hope for Narcotic Addicts . . . The Newer Treatment for Serious Burns . . . Putting Poison in the Pantry . . . The Evil of Extracurricular Activities for the School Child . . . New Light on Inheritance . . . The Great American Tragedy (unsafe driving) . . . The Worst of All Diseases (heart disease) . . . Abdominal

Pain and the Operation . . . United States Political History from a Test-Tube . . . Delicious But Deadly Mushrooms . . . The Problem of Skin Disease . . . The Fourth Horseman (wreckless car driver) . . . Battling the Coryza "Bug" . . . Your Germs and Mine . . . How's Your Rheumatism? . . . Death Fighters.

Should the Public Health Education Section Do Likewise?—Much material from advertising sources is used by schools and by health departments. *How may we decide what is sound and desirable for use, and what is unsound or otherwise undesirable?*

An answer to this question has been sought by the food and nutrition division of American Home Economics Association. A report is presented by the chairman of the committee on illustrative material, entitled "Criteria for Evaluation of Illustrative Material for Foods and Nutrition Teaching," by J. I. Rowntree. The report presents questions and sub-questions to be raised as to

Educational value of the commercial and non-commercial materials and to the appraisal of advertising matter.

Many of the questions about the suitability of the material and its educational value might well be asked about much material issued by health agencies, and the manner of using health education material from any source, such as:

Are posters used mainly to fill space on an uninteresting wall, to give the room a semi-scientific appearance, or are they shown only when they will serve a definite purpose in developing judgment or supplementing information?

Is there one fundamental point which attracts attention, and do all other data support, clarify, and explain that point?

Is the material presented in a vivid manner that readily attracts both the eye and the interest?

Does the form aid in organizing the subject matter presented?

Are well-labeled tables or graphs used to impart essential information?

Does the mass of detail and profusion of material result in a confused or fleeting im-

pression rather than the acquiring of one essential idea?

From the third section, "Appraisal of Advertising Matter, we quote two groups of questions:

Is the information set forth scientifically sound?

Were the claims which are made for the product verified in a sufficient number of laboratories to be conclusive?

Is the product likely to have the same value with human beings on ordinary diets as under the laboratory conditions tested; for example, with rats under experimental conditions on very restricted diets?

Do the claims savor of quackery?

Is the advertiser thoroughly ethical in his relation to the public?

Is he attempting to practice medicine without a license?

Is he prescribing for all kinds of human ills without regard to individual needs, encouraging people in self-medication, and thereby delaying proper treatment?

Is he advocating his products for rheumatism, intestinal disorders, heart abnormalities, and infections that merit other attention?

The committee is continuing its work with Mrs. Jessamine Chapman Williams, Oregon State College, Corvallis, as its present chairman. It will welcome criticisms and suggestions for those who attempt to use the present outline.

The report is supplemented by editorials on "School Use of Advertising Material" and "Advertisements of Medicines," the second quoting the text of 6 general rules announced by Federal Trade Commission as its basis for passing upon the advertising of medicines.

All who feel any concern about the use of commercial material by schools and health agencies will wish to read the report and the editorials. In *Journal of Home Economics*, 101 E. 20th St., Baltimore, Md., Dec., 1934. 30 cents.

Some health workers may try out the proposed criteria and report to the chairman.

The Public Health Education Section may look forward to setting up

criteria for the aid of health agencies as well as schools, with due regard to material coming from orthodox health sources as well as that supplied by advertisers.

Soundness of the statements and the relation of the material to advertising is one problem.

The educational value of the material and its suitability to various audiences calls for consideration in connection with the whole range of material more or less lavishly distributed by health agencies. Could we start with minimum standards as to the physical make-up of printed matter? These standards to say that, lacking them, a piece of printed matter looks so dull or uninviting that it is pure waste to distribute it?

"Two Seats on the Aisle"—Questions put in "Second Balcony":

How many (advertisers, store managers and their kind) make a practice of sitting in second balcony seats when they attend the theatre?

How many sit in the bleachers at the ball game?

How many ride cross country in buses?

How many hang onto the trolley straps when they go about their work in the cities?

Do you? Those are the places where your customers are!

There are to be found those "who buy and buy and buy," says the author.

The sales-minded man or woman may not live with the mass (called "mass" for want of a better name) but he should be part of it. He should mingle with it, listen to it, talk to it.

Read the *'Merk* to enliven your inner life. Hear one of Gertrude Stein's lectures—if you can. But, for your business, remember that the publication that has the biggest circulation in this country is Mr. Hearst's *American Weekly*. And millions of copies of *True Story* are still being sold.

In *Advertising and Selling*, 9 East 38th St., New York, N. Y. Nov. 8, 1934. 20 cents.

The quotations may remind health educators of *their* audiences—not our

friends and associates, not members of boards and committees, not the people we know, but those we are not likely to know unless we are very much on the job.

Good to Read but Not to Look At
—Brevity is not always the soul of good writing. Briefly, the Illinois Society for the Prevention of Blindness might have told in its annual report that 240 trachoma clinics were held, 9,894 attended, and 309 operations were performed. As Miss Audrey Hayden, executive secretary of the society, reports these clinics in three single spaced typewritten pages, the people who attended them emerge as human beings. The amusing, if sometimes disheartening adventures make the clinics more than a routine service. There is an account of the borrowing of rooms for clinics including "the only available room in the courthouse which, at the time it was assigned to us, contained two tons of coal, 1 load of wood and 43 spittoons."

Just as humanly, and also with the spirit of adventure lending excitement to success, Miss Hayden tells of the educational work with midwives and of the sightsaving classes.

This is the "report of the executive secretary"—duplicated for a little extra use among those interested in the society. Even so, we wish that there were some headings to make up, partly for the lively reading by Miss Hayden at the Annual Meeting.

Ask the Illinois Society for Prevention of Blindness, 203 N. Wabash Ave., Chicago, to send you a copy of this report which is dated November 19, 1934.

"Situations Frankly Revealed"—Public relations means just that—relations with the public that lead to confidence and understanding, support and

use of the health organization of any type.

"If it is important," says Violet H. Hodgson, "for the public health nursing organization to analyze the needs and discover the desires of the public," then

It is equally essential that the public understand the objectives, policies, and needs of the organization. This necessitates a broad program of publicity that will keep the public in touch with the program the year round and not merely during the annual drive for funds. Good will must be established and maintained through a high quality of service and a general approval of the policies and program of the organization. Such approval can be expected only when the public has been taken into the confidence of the organization, and situations frankly revealed which make changes in content or administration necessary. Frequently this knowledge is confined to the board and professional staff. The public, as sole stockholder and consumer, is entitled to periodic reports sufficiently frequent to keep them informed of the activities of the organization.

Mrs. Hodgson discusses courtesy and friendliness by staff and volunteers in the home and at clinic or conference as important factors in good public relations. In "Public Relations in Public Health Nursing." *Public Health Nursing*, 50 W. 50th St., New York. Nov., 1934. 35 cents.

When the Horse Changes Color—One angle of the not altogether simple problem of personal publicity for the professional man is illustrated in the following, taken from a state medical journal:

A little group of physicians was discussing the abuse of advertising when the question of pictures in the lay press came up, and one man called the attention of the group to a picture in a local paper of a group of State Association officials, and he inquired as to whether that would not be termed advertising. It seemed to be the consensus of opinion that such pictures were news stories and should not be considered as in any wise unethical, and we believe that is a correct interpretation. It becomes a horse of a different color,

however, when one's picture accompanies an article that is a personal boost, for there really is no necessity for using a picture of a physician along with a tale of his personal prowess.

A Health Education Program for 200,000—Savel Zimand, after several years' experience in Bellevue-Yorkville area, New York City, sets down "An Organized Community Health Program" in *Quarterly*, Milbank Memorial Fund, 40 Wall St., New York, N. Y. Oct., 1934. 25 cents.

The objectives of popular health instruction:

First, it is vital that the community have a general knowledge and understanding of the work of the official health organization. Few people now realize in full the important rôle played by a health department in maintaining the welfare of a city, or the various services, with a direct influence on their own and their family's life, it renders. The public should know how a health department functions; its responsibilities; the services it maintains; when and how they may call upon it for help; what constitutes a violation of health ordinances; and to whom such violations should be reported.

The other objectives might be summarized as follows: Familiarizing the community with facts related to health conservation and disease prevention; securing desirable changes in public opinion, attitudes, and habits on questions of preventive medicine and public health*; creating a desire for new facilities; and educating the community to utilize the medical services of a private physician or, if financially unable to pay for such services, to use those of the community's clinics or hospitals.

While the objective should be a well rounded program, local conditions of the area will help determine which subjects should receive the most emphasis. The formulation of a program for a specific district will de-

pend on research, local surveys, and a study of the vital statistics of the area. In any case it seems important, both because of the numbers affected and the opportunity for preventive work offered, that the program include, in addition to acquainting the public with the work of the health department, such subjects as venereal diseases, tuberculosis, maternal and infant care, diphtheria prevention, child hygiene in general, prevention of colds and pneumonia, dental hygiene, nutrition, the dangers of self-medication and quackery, periodic health examinations, and safety at home and in the street.

Then follows an outline of "Methods," "Machinery," and "Instruments," with sections on "Health Education for the Professional Groups" and "School Health Education."

Probably it would be interesting and it might be profitable for health workers in a city or a district of comparable size to sit down with this outline and check the local activities with this demonstration program.

"Wasn't That a Good Speech?"—Under this title appears a "code for convention speakers." The writer outlines what constitutes a good convention speech.

Naturally, the very first injunction must be *Avoid the obvious*. We all constantly suffer under the so-called eloquence of speakers who labor for the thousandth time educational platitudes that begin to impress us as probably not true, because we have grown so tired of them. . . . And even greater misdemeanor, however, is committed by some would-be clever speakers who take these obvious facts and principles and seek to disguise the obviousness of what they are saying by clothing them in a complicated and bewildering terminology. Disagreeing completely with Shakespeare as to what's in a name, they seem to believe sincerely that a new name for an idea makes it a new idea.

In our own energetic day there are so many really new activities going on and so many points of conflict are involved in these, that it ought to be easy to carry out the second suggestion: *Seek and develop a controversial point*. We are much more likely to interest our hearers if we do so. It is desirable to avoid personalities, to keep the battle on a high plane of principles, but it might be even

* As Mary P. Connolly has stated (Connolly, Mary P.: *Organization of Adult Groups for Health Education. American Journal of Public Health*, 24, No. 6, Part 1 (June, 1934, pp. 571-575): "In addition to personal health advice it is important in this day of too close living that men and women shall learn something about disease communication and how they may safeguard themselves; something of the principles of sanitary science, if only for esthetic reasons; something about child care and behavior which will give their children a better chance."

better sometimes to mention someone by name whose ideas we are attacking and to make the conflict somewhat of a personal one than to omit the element of the controversial.

On the other hand, we are professional men and women, and out of a spirit of fairness it is necessary to *Present both sides*. Show the two pictures, and you will not only be displaying the spirit of fair play, but also be making use of the device of contrast, in itself a useful rhetorical method for securing interest.

We have in the past been so sensitive in the matter of dignity that it is more than difficult for some teachers to observe the fourth injunction: *Be lively*. . . . A little slang now and then will do no harm and there is no question that colloquialisms ought to be pretty freely employed. Talk American—1934 American.

It is very important that the next commandment should be observed: *Reach some definite conclusion*, and avoid detours in reaching it. Many a speech goes wobbling along without purpose for dreary minute after minute and when the orator (save the mark!) is through, no one knows what he has been driving at. The closing passages of the talk should make clear, in vigorous phrasing, what it was all about.

This conclusion will be an especially effective one if the speaker observes the next principle: *Say something practical*. (This may mean concrete advice, or the clearing up of a doubt.)

In these days of confusion of the public mind on the subject of the schools and education, it is well to keep in mind this point: *Prepare your talk so that one particular paragraph of it (say 150 or 200 words) can be used for publicity purposes*. Of course, the publicity must be good publicity and educators would do well to educate themselves on this subject, inasmuch as anyone acquainted with the principles and the psychology of sound public interpretation is likely to be all the better educator. This paragraph should not only contain the nub of your remarks but it should be phrased in a way that will entertain as well as instruct—two ideals by no means mutually exclusive.

The next commandment is very brief: *Stop when you're through*.

The next is also brief and also important: *Revise your talk . . . and cut it down one-third*. You will not hurt anyone's feelings by talking more briefly than you are supposed to talk.

Perhaps the last commandment, in accordance with the Biblical saying, ought really to be first: *Learn how to talk*. One need be

no orator, but certainly any address by a teacher ought at least to be clear in enunciation, careful in pronunciation, and pleasing as to voice. Many a good address is made intolerable by wretched delivery.

Journal, Natl. Education Assn., 1201 16th St., N.W., Washington, D. C. Nov., 1934. 25 cents.

Do Safety Campaigns Fail?—A Los Angeles police official points to a recent campaign to reduce traffic accidents during which "the (traffic) death rate rapidly went up until it was 20 per cent above 1933." Then, when the campaign ended, the rate "went back to normal."

Says *Literary Digest*:

Mr. Steckel deserves credit for his candor, and for his effort to get at the facts, no matter how they conflict with cherished beliefs. Nevertheless, he sounds far too pessimistic. Let him call any experienced editorial writer, advertiser, or press-agent into conference, and he quickly will learn where his error probably lies. These men know that the public's opinion and conduct can be influenced, and are being influenced, constantly, but that, in some instances, at least, it takes time. Frequently, there is a noticeable time-lag between the date when one of their campaigns is launched, and the date when it begins to show results. Usually the results appear, sooner or later, but they may appear in the period following the one in which they are expected.

The Volunteer in Publicity—All too little use has been made of volunteers by public health departments, and too little publicity use has been made of them in the year-round work of private associations.

A plan and a program for volunteers in public health nursing groups is presented by Evelyn K. Davis. In essentials, what Miss Davis offers seems widely applicable.

Some of the headings: "A Plan Essential," "Finding the Job," "Recruiting the Volunteers," "Placing the Volunteers," "Training the Volunteers," "Management." The article is one to be studied and kept for reference.

Publicity and health education in its inclusive sense offers many jobs for volunteers. Some are obvious and easy, some obvious ones depend upon the type of supervision available. Few health organizations have tested the full range of possibilities.

See "The Volunteer—Asset or Liability?" and the accompanying article on "Lay Participation in Public Health Work," by K. H. Trawick. *Public Health Nursing*, 50 W. 50th St., New York. Nov., 1934. 35 cents. A reprint of "The Volunteer" alone, 10 cents.

Pictorial Diagrams—A goodly range of the Neurath type of "pictorial graphs," in black and white, is available in "Modern Social and Educational Trends." This is the Nov., 1934, issue of *Research Bulletin*, National Education Assn., 1201 16th St., N.W., Washington, D. C., 25 cents.

On the 46 pages appear 28 graphs or diagrams, the subjects ranging from age distribution of the population and infant mortality, to growth of national wealth and circulation of daily newspapers.

There are chapters on population and on health and vitality, but most of the

material will interest our readers, and the selection of diagrams will illustrate possibilities of this graphic form when printed in plain black and white. These examples were prepared by the N.E.A. with the assistance of Pictorial Statistics, 150 East 36th St., New York, N. Y.

A sample diagram is reproduced on this page.

It Gives Prices and Addresses--The latest teacher's aid to reach us is "A Nutrition Program and Teaching Outline," "developed for use in the health centers and clinics of the Division of Child Hygiene, Dept. of Public Health, Philadelphia."

Of special interest to this department are the numerous lists of reference and teaching materials. As a rule prices (when not "free") and addresses of publishers are given. The chief exception is "Good Books for Reference (Available in Libraries)." Why not encourage and simplify the purchase of a few of those books by including prices and addresses?

One debatable paragraph reads:

Monthly or weekly publications of various city and state departments of health throughout the country are free on request. They

AGE DISTRIBUTION OF THE POPULATION

Each symbol represents 3 percent of total population

Ops Div., Nat Educ Assn

contain frequent articles on health and nutrition work pertinent to locality. New York City and Chicago Departments of Health have various attractive helpful publications.

One cannot but speculate as to the probability that "various city and state departments" will welcome requests from people outside of their respective territories.

The book should be useful in connection with emergency relief nutrition activities. Address Philadelphia Child Health Society, 311 S. Juniper St., Philadelphia, Pa. 156 pages. \$1.00.

Popular Health Topics in Hygeia—*Hygeia*, published by American Medical Assn., 535 N. Dearborn St., Chicago, Ill., for Dec., 1934, included the following and other material usable in numerous ways (single copy free to a health worker):

Human sterilization Sickness insurance and sickness costs The making and unmaking of a quack (part I) The meals of yesterday The psychology of the middle years The flea Physical examinations The problem of anemia Nobel prize winners in medicine (with portraits) The Wassermann test Speech problems in childhood Committee acceptance of sweets, sugars, and syrups Structural abnormalities of the eye Tuberculosis and the kings of France School and health, including Why measure

health teaching How can we judge the results of health teaching?

MAGAZINE ARTICLES

"Accidents Don't Just Happen," by F. Brutto. *Kiwanis Magazine*, 520 N. Michigan Ave., Chicago, Ill. Nov., 1934. 15 cents. "In Evanston (Ill.) accidents don't just happen. Neither did Evanston's record (of prevention) just happen." Material here for local articles all over the country.

"Buying Health" is the theme for the Dec., 1934, issue of *Survey Graphic*, edited by Mary Ross. Here is set up the problem as viewed from various angles—as officially stated by the leading organized groups—as interpreted by representatives of the groups most concerned. 30 cents. 112 E. 19th St., New York, N. Y.

"Health Insurance." *Nation*, 20 Vesey St., New York, N. Y. Dec. 12, 1934. 15 cents. "Health insurance is the most immediately practicable and financially possible form of economic-security legislation."

"Pity Poor Elizabeth Barrett! of Wimpole Street, Imprisoned in an Airless Room, Waiting for Death from Tuberculosis." Interesting and effective use of the well known poet to point the health moral. In *Everybody's Health*, 11 W. Summit Ave., St. Paul, Minn. Dec., 1934. 10 cents.

BOOKS AND REPORTS

Webster's New International Dictionary of the English Language, (2nd ed.). Unabridged. William Allan Neilson, Editor in Chief; Thomas A. Knott, General Editor; Paul W. Carhart, Managing Editor. Springfield, Mass.: G. & C. Merriam Co., 1934. 3210 pp. Price: \$20.00 to \$35.00 according to paper and binding.

One approaches the reviewing of a monumental achievement such as Webster's New International Dictionary with hesitancy. A review in the ordinary sense of the term is practically impossible.

The second edition of the well known Webster's Dictionary, which has since 1909 been called The New International, is the result of 10 years' work by 207 editors under the general supervision of Dr. William Allan Neilson, as Editor in Chief, and Dr. Thomas A. Knott, formerly Professor of English at the University of Iowa, as General Editor. It has more than 600,000 entries, 550,000 of which are in the vocabulary. There are 13,000 biographical entries and 35,000 entries in the Pronouncing Gazetteer.

The book opens, as did former editions, with the reproduction in color of the flags and arms of all nations, state flags and seals, etc. There are money tables, tables of weights and measures, signs used in writing and printing in the various arts and sciences, proof reading, and a vast amount of other information needed in everyday life, such as forms of address, and abbreviations, of which there are 5,000.

The writer, in editorial work, has occasion to read papers by those engaged in 10 different specialties and

these necessarily bring in many terms used in allied sciences. This review is therefore chiefly concerned as to the value of the work to the scientific man. Criticism from the literary and philological standpoints is left to specialists.

As has been pointed out in reviews of medical dictionaries in these columns, one can only select a number of test words. In looking these up one can judge of the clearness of expression, the ease of locating the information desired and the completeness of the references. These tests have been applied to a large number of terms, many of them quite new. The vocabulary of such terms is unusually full and surprisingly up to date. Lexicographers are necessarily somewhat slow in adopting new words and sometimes carry this caution to an extreme. Very few such instances have been discovered in the present work.

Under abbreviations, the many alphabetical names which have had their birth with the New Deal are given. However, as pointed out by some reviewers, "brain trust" and "crack-down" have not made the grade, though "applesauce" and "hot dog" have.

One of the chief differences in the make-up of this edition from the preceding one is the number of words which have been transferred from the "Lower Section" of the pages to the regular vocabulary. These are standard English words, except as indicated by usage labels, as obsolete, slang, etc.

There are 48 full-page plates, 32 of which are in colors, and 12,000 terms are pictorially illustrated. The History of the English Language, to which 58 pages of the introduction are given, can be especially commended. The printing and binding are excellent.

Webster has been for many years the standard of the *American Journal of Public Health*. All questions of spelling, pronunciation, usage, and meaning are settled by this Dictionary. While the present writer cannot speak for future editors, it is safe to say that as long as the publishers show the same enterprise as has been shown for more than 100 years, it will continue to be the standard reference for this *Journal*. Having seen and used the new edition, one wonders how it was possible to get on without it.

The Dictionary is obtainable in a number of bindings to suit the purse of everyone. The publication of this work was celebrated by the assembling of some 300 scholars and educators at a dinner in Springfield, Mass., at which the Editor in Chief and the General Editor presented the book to President Asa George Baker and Robert C. Munroe of the Merriam Company, and they in turn presented it to the world.

MAZÛCK P. RAVENEL

How to Succeed in Life—By Grenville Kleiser. New York: Funk & Wagnalls, 1934. 330 pp. Price, \$2.00.

An author who has produced no less than 28 other books, mostly on public speaking, offers in this somewhat jejune volume a procedure for the attainment of that elusive condition popularly known as "Success." In 8 chapters of approximately 40 pages each he advises his readers how to plan, sleep, eat, think, work, serve, do, and live well. None of it is very profound. There is no index.

JAMES A. TOBEY

Exercise Without Exercises—By S. Arthur Devan. New York: Dodd, Mead, 1934. 84 pp. Price, \$1.25.

This brief text seems built about the idea that the secret of good health rests in good posture (centered about the primary school idea of standing and

sitting "tall"), proper walking and breathing, and special development of abdominal muscle movements.

Although the author's knowledge of physical education apparently dates in the 19th century—he talks of "physical culture" and "physical culturists"—there are some good hints for the layman.

CHARLES H. KEENE

Physical Defects—The Pathway to Correction—*American Child Health Association, 50 West Fiftieth Street, New York, N. Y., 1934. 171 pp. Price, \$1.00.*

Here is enlightening research into the administrative methods of present school health programs. This book is particularly valuable in that it does not content itself with generalizations but offers definite conclusions and practical suggestions based on concrete facts. It is a specific answer to a specific question: "Why do so many school children continue to suffer from severe, uncorrected physical defects?" Since this question is being asked in so many communities, the answer suggested in this study is of interest to administrators of school health services throughout the country.

The writers of *Physical Defects—The Pathway to Correction* base their findings and conclusions not on theories but on direct inquiries in schools and homes. In the course of the study, research experts examined 25,000 children in 121 schools and talked with 579 teachers, 95 school nurses and with parents in 1,800 homes. The history of each child with a severe defect was checked, as completely as possible, from the time of his first school health examination. In this way the investigators discovered exactly where, when, and why he was dropped from the pathway to correction.

The most important finding is that, in general, school health services are attempting to carry on a much more

extensive program than can possibly be well done with funds and personnel available for it. The conclusions contain specific prescriptions for carrying on a more scientifically selected, and therefore more effective, program.

Every public health administrator, with any interest in school health service, should make specific use of the definite, practical suggestions and conclusions of this book.

CARL E. BUCK

On the State of the Public Health.

Annual Report of the Chief Medical Officer of the Ministry of Health for the Year 1933. *London: His Majesty's Stationery Office, 1934.* 295 pp. Price, 4s. 6d net.

The annual report of Sir George Newman is always interesting reading and the "Conclusions" are a liberal education in public health. This one is no exception.

There was a decrease in the births registered, to 580,413 against 613,972 in 1932—the lowest birth rate on record. Infant mortality fell from 65 to 64 per 1,000 births. There were 496,465 deaths against 484,129 in 1932. Suicides decreased by 89, or 1.5 per cent. There were 7,986 more violent deaths, chiefly road accidents, attributed to pedal cycles, than in 1932. Of 205,037 injuries and fatalities, 74,769 were "pedestrians."

The most promising field for improvement in the death rate from 15 to 20 lies principally in the prevention of tuberculosis among both sexes, and death due to accidents among males. While the tuberculosis situation has improved (death rate from pulmonary tuberculosis 993 per million in 1921–1930 to 799 in 1933), the relative slower rate of decline, or even a rise, in young women between 15 and 25 years, continues to give concern. It will be remembered that the appointment of authorized agents as tuberculosis officers

was recommended to coördinate under the Medical Officer of Health the various anti-tuberculosis activities. There are now in England and Wales 380–390 such officers, 459 tuberculosis dispensaries, and 26,773 sanatorium beds, against 5,700 in 1911.

Sir George refers to statements made now, as in 1904 and also in 1918, that as a race the English are deteriorating, that there is increase in the deaths attributed to cancer, heart disease, and preventable accidents, that large numbers of children are physically and mentally defective, that the physical condition of the recruits of the Army leaves much to be desired, that the maternal mortality remains practically the same and the nutrition of the people is not as good as it should be. Admitting the truth of some of these statements, on the whole he denies them. The improvement in the mortality rate 1–5 years is greater than that recorded in the first year of life, and from 15 to 20, the rate for 1921–1930 is only 39 per cent of that for 1861–1870. He considers that the evidence, taken as a whole, indicates that general health and nutrition was well maintained in spite of the economic and social difficulties, and that the health of the unemployed and their dependents is not suffering seriously or generally, though he recognizes the physical, mental, and social impairment associated with long unemployment. He does not claim that nutrition is as good as it might be for all, or that it is not capable of improvement. Education has done a great deal. The purchasing power of wages increased in 1933, and foods became cheaper, more available, and more varied, including an enormously increased consumption of fruits, apples, oranges, bananas, vegetables, eggs, fish, and dairy products.

Altogether the report is optimistic. We wish it were possible to give more space to it, and recommend its study.

MAZÛCK P. RAVENEL

The Housing Program of the City of Vienna—By *Charles O. Hardy and Robert R. Kuczynski*. Washington: *The Brookings Institution*, 1934. 143 pp. Price, \$2.00.

This is a timely presentation of a study of one of the most remarkable social experiments of modern times. Vienna's housing conditions have always been below the standard of large cities in Europe and America and for 20 years before the war there was almost continuous agitation for its reform. Taking an active part in this agitation was the public health group which rested its case chiefly on the efficacy of air and light as foes of tuberculosis. Not until after the war, however, did public housing construction become a necessity and an important part of the program of the Social Democratic party which then came into power in Vienna. The ideal professed by this party is the general principle that housing is a public service to be rendered without charge as are school houses, hospitals, and jails. In their actual program, however, capital costs but not operating expenses were taken into consideration. These costs averaged as low as \$16 per year in rent for apartments consisting of living room, sleeping room, and kitchen. Central bathing facilities were provided in the larger apartment units which the authors estimate were run at much less than full capacity averaging 11 baths per person per year.

The natural questions as to whether party members were favored in allocation of dwellings the authors have answered to their satisfaction. People are human everywhere.

Public health workers in this country have been on the whole peculiarly apathetic to problems of housing. True, the New York State Department of Health assisted in drafting a model building code for adoption by cities and villages in the state. But experience in Great Britain would indicate that

American health officials must concern themselves with the problem of housing if they are to control disease most effectively. Incidentally, Great Britain is now demonstrating that the housing problem can be solved with private capital.

Health officers, engineers, and social workers will find this book most useful in clarifying thoughts on a question which must concern them in an increasing measure. It points out many of the incidental problems that we must solve before advancing in the field of planned housing.

The subject is presented, logically, clearly and interestingly. The book would be helped by a more detailed index.

HOMER N. CALVER

O Problema de Limpeza Publica—By *Lincoln Continentino, C.E.* *Bello Horizonte: Imprensa Oficial de Minas Geraes*, 1932. 344 pp.

The author, a former professor of the Engineering School of the University of Minas Geraes and at present Chief State Sanitary Inspector, in writing his book, had chiefly in mind the collection of data which might help municipal authorities and experts in his country in solving a problem, refuse disposal, facing all towns both in its sanitary and esthetic phases. For that purpose, he has drawn on his own observations when taking a post-graduate course in the United States and on the available literature. In accordance with accepted style, the subject is studied by him under the four headings of home preparation, collection, separation and classification, and disposal. Street cleaning is considered in a separate section. Methods in use in some American and European cities are discussed. The latter are considered preferable since they depend on cremation and do not stress, as in the United States, the use of products of the conversion, with its

hygienic disadvantages. Since the subject is, as a whole, conservatively handled, the book should prove useful for informative purposes to the audience for which it is intended. A number of photographs (not especially well produced) and diagrams add to the value of the work.

Regrets are expressed that Americans, with their recognized leadership in sanitary engineering, seem apparently to lag behind Europe in the field of refuse disposal, and even admit that Germany and England are more advanced in this respect.

To the few American readers familiar with Portuguese the most interesting part will be that dealing with conditions in Brazilian towns as Rio, São Paulo, Recife and Bello Horizonte. A questionnaire sent to other cities remained unanswered.

A deserved tribute is paid to Saturnino de Britto and his pioneer work in providing Brazilian cities with water supplies and sewage disposal systems.

Altogether this is a meritorious book which within its scope must contribute to the development of sanitary engineering in Brazil. A. A. MOLL

A SELECTED PUBLIC HEALTH BIBLIOGRAPHY WITH ANNOTATIONS

RAYMOND S. PATTERSON, PH.D.

Laboratory Experiments With Influenza—Mice are susceptible to the virus of human (and swine) influenza. The virus, when isolated from mice, is neutralized by anti-serum from other animals.

ANDREWES, C. H., *et al.* The Susceptibility of Mice to the Virus of Human and Swine Influenza. *Lancet* 2, 16:859 (Oct. 20), 1934.

Men, Mice and Microbes—The biology of the host-parasite relationship is discussed in illuminating detail, most of which is entirely foreign to the thinking of work-a-day sanitarians.

BREWER, D. The Development of the Theory of Epidemics During the Present Century. *Pub. Health* 48, 2:69 (Nov.), 1934.

Why Slums Must Go—An attempt is made to trace specific directions in which poor housing affects health. Among the many reasons are impure water supply, insanitary sewage disposal, lack of private toilets and sewer connections, overcrowding, lack of light and air, dilapidation.

BRITTEN, R. H. The Relation Between Housing and Health. *Pub. Health Rep.* 49, 44:1301 (Nov. 2), 1934.

Amebic Dysentery Controlled—Briefly reviewed is the whole story of the late Chicago amebic dysentery epidemic, illustrating well the danger of accepting conclusions unchallenged, and showing the difficulties involved in completely reorganizing epidemiologic procedure. A stimulating paper.

BUNDESEN, H. N. The Chicago Epidemic of Amebic Dysentery in 1933. *Pub. Health Rep.* 49, 43:1266 (Oct. 26), 1934.

What To Do With Garbage—The failings of present methods of garbage collection and disposal serve as an introduction to the second paper which discusses the feasibility of home disposal of food wastes ground and flushed into sewers. It would be fine for apartment dwellers if the sewage works could stand the extra load.

COHN, M. M. The Dual Disposal of Sewage. *Municipal Sanitation.* 5, 10:332 (Oct.), 1934 (and) 5, 11:368 (Nov.), 1934.

All Colds Are Not Alike—Epidemiological differences exist between head colds, sore throats and chest colds when the presence of fever is considered in relation to the type of infection.

COLLINS, S. D., and GOVER, M. Age and Seasonal Incidence of Minor Respiratory Attacks Classified According to Clinical Symptoms. *Am. J. Hyg.* 20, 3:533 (Nov.), 1934.

Sex Differences in Pneumonia Mortality—During childhood more boys than girls die of pneumonia, due presumably to inherited susceptibility. The difference disappears temporarily at puberty. In adolescent years excess rates for males are presumably due to a variety of factors. From 20 to 69 the male death rate excess may be attributable to occupational hazards, for the male excess disappears in certain rural regions. In old age the female rate usually is greater than the male, probably because only the tough men are left.

DOULL, J. A., *et al.* The Sex Ratio of Pneumonia Mortality and Its Possible Relation to Occupation. *Am. J. Hyg.* 20, 3:628 (Nov.), 1934.

Why Bowels Balk—Dosing from infancy onward and bad habits, more than insufficient bulk in diet, are the causes of constipation. The Friday night purge is as much an institution as the Saturday night bath in most British families favored with youngsters.

GREGORY, H. H. C. The Prevention of Constipation in Children. *J. State Med.* 42, 11:632 (Nov.), 1934.

More Arguments For Pasteurization—Five outbreaks of food poisoning from which staphylococci were isolated are added to the record. No uniform biological or serological characteristics are evident. Raw milk and cream and human contact are the most likely vectors.

JORDAN, E. O., and BURROWS, W. Further Observations on Staphylococcus Food Poisoning. *Am. J. Hyg.* 20, 3:604 (Nov.), 1934.

Does Childhood Tuberculosis Protect?—The initial tuberculosis infection carries a double liability: the bacilli remain alive indefinitely and liable to be set free; the allergy resulting from the first invasion converts the comparatively harmless protein of succeeding tubercle bacilli into a virulent poison.

MYERS, J. A., and HARRINGTON, F. E. The Effect of Initial Tuberculous Infection on Subsequent Tuberculous Lesions. *J.A.M.A.* 103, 20:1530 (Nov. 17), 1934.

Errors in Phenol Coefficients—Any small deviation from prescribed conditions for determination of survival times in phenol coefficient tests may produce differences in the resistance of the culture. Errors may be large for slight deviations in technic. A 1° difference in temperature of incubation of the culture will cause a significant difference in its resistance to phenol. A two-hour difference in the age of the culture is significant when tests are made at 15 second intervals, and a four-hour difference in age will affect results from 5 minute interval tests.

SMYTH, H. F., Jr. Evaluation of Some

Factors Influencing the Phenol Resistance of Staphylococcus Aureus. *J. Bact.* 28, 4:333 (Oct.), 1934.

Agglutinin Response to Vaccine—O agglutinin formation takes place as readily with suitable anti-enteric vaccines as it does during enteric disease. However, a better response is obtained with freshly prepared antigens than with those that have been exposed to the usual concentrations of phenol even for a short time.

STUART, G., and KRIKORIAN, K. S. Agglutinin Response to Recent Anti-Enteric Vaccination. *Lancet* 227, 5795:644 (Sept. 22), 1934.

Varieties of Typhus Fever—Brills disease is an imported form of European louse-borne typhus fever and is distinct from the Mexican rat-flea-borne type of the disease.

ZINSSER, H. Varieties of Typhus Virus and the Epidemiology of the American Form of European Typhus Fever (Brills Disease). *Am. J. Hyg.* 20, 3:513 (Nov.), 1934.

Pro BCG—Calmette's vaccine prevents tuberculous infection in the exposed infants under observation, reports this Swedish researcher.

WALLGREN, A. Value of Calmette Vaccination in Prevention of Tuberculosis in Childhood. *J.A.M.A.* 103, 18:1341 (Nov. 3), 1934.

Birth Reporting Deficiencies—Estimates of the completeness of birth reporting in each state are of great value to anyone using statistics seriously. Some states have practically perfect reporting, but others have obviously slumped since admission to the Registration Area. Nineteen were estimated to rate below 90 per cent completeness in 1930. One state showed only 72 per cent completeness for whites and 30 per cent for colored. Infant mortality rates are lowered appreciably through use of the author's corrected birth figures.

WHELPTON, P. K. The Completeness of Birth Reporting in the United States. *J. Am. Stat. Assn.* 24, 186:125 (June), 1934.

ASSOCIATION NEWS

SIXTY-FOURTH ANNUAL MEETING

MILWAUKEE, OCTOBER 7-10, 1935

Headquarters: Hotel Schroeder

COMMITTEE ON PROFESSIONAL EDUCATION MEETING

A MEETING of the Committee on Professional Education was held in New York on December 8. It will be remembered that this committee is charged with the carrying out of research and the development of standards for professional education and training in public health work, and the performance of necessary activities with a view to maintaining professional qualifications of high standard.

Accordingly, the committee, through its various sub-committees, has been giving consideration to the problem of minimum qualifications and training of health officers, sanitary engineers, sanitary inspectors, and public health nurses. It is hoped in time to extend

these studies to other professional groups. Studies in coöperation with other agencies have been carried on to determine minimum requirements which it is felt persons entering the public health field should possess.

The committee has concerned itself with the question of teaching preventive medicine in medical schools, and is hopeful that a plan may be worked out to interest institutions in the desirability of giving increased consideration to this problem.

It is planned to hold another meeting of the committee early in the summer and to consider recommendations for presentation at the Milwaukee Annual Meeting.

COMMITTEE ON RESEARCH AND STANDARDS MEETING

THE Executive Committee of the Committee on Research and Standards met in New York on December 6 and devoted considerable time to the question of the status of various standards of the Association.

It is planned to publish in an early issue of the *Journal* a list of Association publications and standards, indicating their present status, and in many instances the expected date of revision. Such a statement should prove of value to the membership, since the standards in question cover

many phases of public health work.

The Sub-Committee on Communicable Disease Control is actively engaged in a revision of the pamphlet on Communicable Diseases, and hopes to have it available within a few months.

The referee on Shellfish Examination reported that a revision of Standard Methods for the Examination of Shellfish will be undertaken during the year.

The committee has also interested itself in many other pertinent problems, and will follow an ambitious program during the coming year.

APPLICANTS FOR MEMBERSHIP

The following individuals have applied for membership in the Association. They have requested affiliation with the sections indicated.

Health Officers Section

- Samuel G. Arnold, M.D., 209 City Hall, Long Beach, Calif., Health Officer
 Nolton N. Ashley, M.D., City Hall, Oakland, Calif., City Health Officer
 Albert M. Price, C.P.H., 1580 Jackson St., Charleston, W. Va., Director of Rural Sanitation, State Department of Health
 Claude A. Thomas, M.D., 212 W. Burke St., Martinsburg, W. Va., Berkeley County Health Officer
 Edward P. White, M.D., Gaffney, S. C., Director, Cherokee County Health Department

Vital Statistics Section

- Edward B. Bosworth, C.P.H., 121 Whitney Ave., New Haven, Conn., Statistician, Department of Health

Public Health Engineering Section

- Roy B. Everson, 627 W. Lake St., Chicago, Ill., Everson Filter Company
 Fujio Kashiwara, 701 W. Illinois St., Urbana, Ill., Assistant Sanitary Engineer, South Manchuria Railway Company

Industrial Hygiene Section

- Violet H. Hodgson, Department of Health, White Plains, N. Y., Director, Division of Public Health Nursing
 Francis R. Holden, Ph.D., Belle Field Apts., Detroit, Mich., Chemist, Industrial Health Conservancy Laboratories.

Food and Nutrition Section

- Francis P. Griffiths, M.S., Department of Bacteriology, Mass. State College, Amherst, Mass., Junior Bacteriologist, U. S. Bureau of Fisheries
 William E. Krauss, Ph.D., Ohio Agr. Experiment Station, Wooster, O., Research Worker in Nutrition
 Minna Stitch, Hunter College, Bronx Bldgs., Bedford Park Blvd. & Navy Ave., New York
 Mark H. Wodlinger, 400 W. Madison Street, Chicago, Ill., President, American Research Products, Inc.

Child Hygiene Section

- Marguerite M. Hussey, Ph.D., Box 45, Park Ridge, N. J., Teaching in School of Education, New York University

Public Health Education Section

- Violet R. Ward, B.A., 54 Stratford Rd., Berkeley, Calif., Supervisor of Health Education, Berkeley School System

Public Health Nursing Section

- Lydia R. Sheall, R.N., 1806 Maple Ave., Evanston, Ill., Superintendent, Visiting Nurse Assn.
 Juanita R. Zamora, Thermal, Calif., School Nurse

Epidemiology Section

- Henry T. Dean, D.D.S., U. S. Public Health Service, Washington, D. C., Dental Surgeon
 Salvador Riera-Lopez, M.D., C.P.H., Department of Health, San Juan, P. R., Epidemiologist

DECEASED MEMBERS

- H. L. Akridge, M.D., Brunswick, Ga., Elected Member 1923, Fellow 1929
 W. G. Hollingworth, D.V.S., Utica, N.Y., Elected Member 1919, Fellow 1926
 Vernon Robins, M.D., Louisville, Ky., Elected Member 1916, Fellow 1922
 F. W. Sears, M.D., Syracuse, N. Y., Elected Member 1914, Fellow 1922
 Dr. John H. Blanks, Zion, Ill., Elected Member 1925
 E. Pauline Bledsoe, McPherson, Kans., Elected Member 1933
 Nelson C. Davis, M.D., Bahia, Brazil, S.A., Elected Member 1923
 George W. Hunter, Ph.D., Claremont, Calif., Elected Member 1928
 Fred J. MacDonald, M.D., Schenectady, N. Y., Elected Member 1931
 Paul F. Nichols, M.S., Berkeley, Calif., Elected Member 1934.
 Dr. James M. Parrott, Raleigh, N. C., Elected Member 1932
 Charles V. Roman, M.D., Nashville, Tenn., Elected Member 1926

NEWS FROM THE FIELD

OHIO FEDERATION OF PUBLIC HEALTH OFFICIALS

THE Ohio Federation of Public Health Officials held its annual meeting at the Deshler Hotel, Columbus, Ohio, November 14-16, in co-operation with the Ohio Health Commissioners Conference conducted by the State Department of Health.

The following officers were elected:

President, Dr. W. G. Rhoten, Wooster

Vice-President, Dr. A. G. Sturgiss, Marietta

Secretary-Treasurer, Dr. W. D. Bishop, Greenville

Representative on the Governing Council, A.P.H.A., Dr. G. D. Lummis, Middletown.

The principal speaker for the Federation was Dr. Joseph Mountin of the U. S. Public Health Service, who has been in Ohio for some time making a study of Health Administration in county government. His subject was "Public Health Administration under County Government Amendment."

The attendance at this meeting was approximately 350, representing health commissioners, nurses, and sanitary officers.

MICHIGAN'S PUBLIC HEALTH CONFERENCE

THE Fourteenth Annual Public Health Conference of the Michigan Public Health Association and the Michigan Department of Health, held in Lansing on November 7-9, attracted a record attendance of 440 health officers, public health nurses, sanitary officers, and laboratory workers. All but 15 of the state's 83 counties were represented, Wayne County sending 70 members.

Officers of the Michigan Public Health Association elected at the Annual Business Meeting are as follows:

President—Dr. B. W. Carey, Detroit

Vice-President—Dr. G. M. Byington, Battle Creek

Secretary-Treasurer — Marjorie Delavan, Lansing

Directors for 2 year terms—Dr. V. K. Volk, Pontiac; Dr. William R. Davis, Lansing; and Mrs. Hugh Gaston, R.N., Sault Ste. Marie

Representative on Governing Council of A.P.H.A.—Dr. C. C. Slemmons, Lansing

MEETING OF WEST VIRGINIA PUBLIC HEALTH ASSOCIATION

THE recent Annual Meeting of the West Virginia Public Health Association, held jointly with the Public Health Officers' Conference, was in every way successful, with an attendance of 350-400 health workers from all fields.

The following officers were elected for 1935:

Dr. T. E. Cato, *President*—New Cumberland

Dr. A. J. Kemper, *First Vice-President*—Clarksburg

Dr. E. R. Davies, *Second Vice-President*—Kingwood

Dr. John Thames, *Secretary-Treasurer*, Charleston

Dr. John Thames, *Representative on Governing Council*, A.P.H.A., Charleston

FLORIDA PUBLIC HEALTH MEETING

THE sixth annual meeting of the Florida Public Health Association was held in Jacksonville, Fla., December 3-5, at the Mayflower Hotel.

The following officers were elected:

President—George N. MacDonnell, M.D., Miami

First Vice-President—N. A. Upchurch, M.D., Jacksonville

Second Vice-President—Johanna L. Sogaard, Jacksonville

Secretary-Treasurer—Stewart G. Thompson, D.P.H., Jacksonville

The program was of unusual interest and included important papers from many leading authorities from various states. The meeting was called to order by the President, Dr. J. R. McEachern, who is City Health Officer of Tampa.

Dr. McEachern's presidential address will appear in the January number of the *Florida Health Notes*. Some of the titles of papers presented were:

Pulmonary Spirochetosis; County Health Units; Early History of Vaccination Against Smallpox; Rural Health Service; Some Health Problems Regarding Parasitic Diseases Transmitted by Insects; Dengue in Miami; Significance of Dengue Epidemic; Food Inspection; Pellagra; Public Health Nursing; FERA Social Service and Public Health Program; Nursing Among Seminole Indians; Screw Worm Infestation in Florida; Progress in Sand Fly Control.

NATIONAL ACADEMY OF MEDICINE OF MEXICO ELECTS OFFICERS

THE newly appointed officers of the Academia Nacional de Medicina de Mexico are:

President, Francisco de P. Miranda, M.D.

Vice-President, Dr. Gustavo Baz

Permanent Secretary, Dr. Alfonso Pruneda
Annual Secretary, Miguel E. Bustamante,
Dr.P.H.

Treasurer, Dr. Ramón Pardo

Dr. Miranda and Dr. Bustamante are members of the A.P.H.A.

CONFERENCE ON CHILDREN'S NEEDS

THE National Conference on the 1935 Needs of Children will be held under the auspices of *The Parents' Magazine*, January 3-4, at the Pennsylvania Hotel, New York.

Among the speakers will be Fiorello H. LaGuardia, Mayor of New York, on "Child Labor Must Go Forever"; Miss Grace Abbott, Retiring Chief, U. S. Children's Bureau, on "The Forgotten Child"; Aubrey Williams, Assistant Federal Relief Administrator,

on "Children of the Unemployed"; Owen R. Lovejoy, Secretary of the Children's Aid Society of New York, on "Homeless Boys and Girls on the March."

AMERICAN STUDENT HEALTH ASSOCIATION MEETS

THE Fifteenth Annual Meeting of The American Student Health Association was held in New York December 27-28, in conjunction with The College Physical Education Association, The American Football Coaches' Association, and The National Collegiate Athletic Association.

INTERNATIONAL NURSING REVIEW DISCONTINUED

THE President of the International Council of Nurses, of Geneva, Switzerland, advises that with the issue of Volume IX of *The International Nursing Review*, dated 1934, further publication of that *Review* has been indefinitely suspended, pending the decision by the Board of Directors as to the further policy they propose to adopt with reference to the same. The question will come before the Board at their next meeting in 1935.

Subscriptions which have been received in advance will be held in suspense until the Board have arrived at a decision with regard to the future of this publication.

AMERICAN FOUNDATION FOR THE BLIND

THE cornerstone has been laid of the new home of the American Foundation for the Blind, at 15 West 16 St., New York.

Speakers at the ceremonies held on December 5 included: Dr. John H. Finley; Helen Keller; M. C. Migel, who gave the land and the 3-story building; and H. R. Latimer, of the Pennsylvania Association for the Blind of Pittsburgh.

Dr. Finley read a letter from President Roosevelt saying he was "very happy indeed to accept the honorary presidency of the American Foundation for the Blind." A telegram was also received from the President, too late to be read at the ceremony.

Into a copper box, placed within the cornerstone, were put autographed photographs of Miss Keller and Mrs. Anne Sullivan Macy her teacher, a talking book record of Mr. Migel's remarks, reports of the Foundation since its origin in 1923, copies of the publication, *Outlook for the Blind*, newspapers for Dec. 4 and 5, and several coins.

At a meeting which followed, Mr. Migel was reelected president of the Foundation; Prudence Sherwin, vice-president; Dr. Burritt, secretary, and Mr. Ziegler, treasurer.

HOW DOCTORS HELP INDUSTRY

A MAN hiring into our shops is medically examined and given work that fits his condition. Disability does not necessarily bar him from a job. Twenty per cent of our present workmen are in the physically disabled class. Some are blind, some deformed, some not very strong—there are twelve thousand of them in all—and each man's work is selected to fit his case. Tuberculous men have sheltered places in the open air. By a system of medical transfers men's jobs may be changed at any time for health reasons.

Our doctors daily inspect all food served to the men and see that lunches are eaten under proper conditions. Even oil used in the machinery is treated with an antiseptic solution to prevent infection of hands or arms. When the bacteria count of the oil in a machine pit is high, the pit is drained, scalded with live steam, and thoroughly scrubbed. In some instances a protective ointment is provided which men rub

on their hands and arms before commencing work. There are many such precautions. . . .— *How Doctors Help Industry*, Radio Talk, W. J. Cameron Ford, Sunday Evening Hour.

CHILD HEALTH CONFERENCES IN IOWA NEXT YEAR

AT the invitation of the University of Iowa, the Eighth Health Education Conference of the American Child Health Association will be held in Iowa City, June 19–22, 1935.

The Conference will be held in conjunction with the Ninth Annual Iowa Conference on Child Development and Parent Education, which is scheduled for June 17–19.

TERM OF BALTIMORE HEALTH COM- MISSIONER EXTENDED

UNDER a recent amendment to the city charter, the term of the Health Commissioner of Baltimore is now 6 years instead of the previous 4-year appointment. It provides that Dr. Huntington Williams's term will expire October 1, 1938, instead of October 1, 1935. The change was a part of the charter revision program sponsored by Mayor Jackson, and will, he expects, take the position of health commissioner out of politics.

The amendment also makes it mandatory for a candidate for this office to have at least 5 years' actual experience in public health work performed by departments of federal, state or municipal governments.

BAD HOUSING

IT has been stated by N. H. Engle, of the U. S. Bureau of Foreign and Domestic Commerce, that—

In 64 cities more than 600,000 homes had neither bathtub nor shower, and nearly 450,000 were without indoor water closets. These figures comprise 23 and 17 per cent respectively of all residential units surveyed.

In a recent statement, Clarence E. Pickett, of the Division of Subsistence Homesteads, U. S. Department of the Interior, said:

While we have built the façade of abundant production higher and higher until its foundations became inadequate to sustain it, we have neglected consideration for the effect of bad housing . . . upon health and upon family life.

—*Public Housing Progress*, Nov. 15, 1934.

THE SLUM PROBLEM

ONE-THIRD of our countrymen are living in scattered hovels, in cluttered shacks, in the squalid flats of congested centers, with common toilets, with dark rooms on fetid shafts; we know from statistics that they are easy victims of chronic ailment and devastating disease, contributing to juvenile delinquency, to gang crime, to gang politics. Such is the slum problem.—*Public Housing Progress*, Nov. 15, 1934.

PERSONALS

HENRY R. O'BRIEN, M.D., A.P.H.A., of Oberlin, Ohio, formerly Health Commissioner of Lorain County, Ohio, has been appointed Assistant District Health Officer of the New York State Department of Health.

WILLIAM A. HOWE, M.D., member A.P.H.A., Chief of the Medical Inspection Bureau of the New York State Education Department, retired October 1, after being associated with the department since 1915.

PHILIP J. RAFLE, M.D., member A.P.H.A., of the New York State Department of Health at Albany, has been appointed temporary District Health Officer with headquarters in Syracuse to succeed the late Dr. Frederick W. Sears.

DR. JAMES A. FAULKNER, of Belleville, Ont., has been appointed Minister of Health for Ontario, Canada, succeeding Dr. John M. Robb, member A.P.H.A.

DR. STANLEY R. PARKINSON, of Marysville, Calif., succeeds Dr. James H. Barr as Health Officer of Yuba County.

DR. DENVER D. ROOS has been appointed Health Officer of Corona, Calif., following the retirement of Dr. William S. Davis.

WILLIAM C. FOWLER, M.D., member A.P.H.A., of Washington, D. C., Health Officer of the District since 1918, retired as of Nov. 24. No successor to Dr. Fowler has been announced, but Dr. Edward J. Schwartz will be acting Health Officer.

ERNEST L. STEBBINS, M.D., member A.P.H.A., has resigned as Health Officer of Henrico County, Va., to join the staff of the New York State Department of Health, at Albany, N. Y.

DR. CHARLES NORRIS, who has been Chief Medical Examiner of New York City since 1918, was presented with a gold medal by the New York Academy of Medicine for his outstanding work in forensic medicine. Dr. Norris entered the city's service in 1904.

DEATH

NOTICE has been received of the death of Lemar M. Andrews, M.D., Health Officer of Warsaw, N. Y., member A.P.H.A.

CONFERENCES

Mar. 27–29, Canadian Section, American Water Works Association, London, Ont., Canada.

Number 2

Value of the Fluoroscope in Pulmonary Tuberculosis Case Finding*

HAYNES HAROLD FELLOWS, M.D.

*Assistant Medical Director, Metropolitan Life Insurance Company,
New York, N. Y.*

IN the early part of 1927 we in the Medical Division at the Home Office of the Metropolitan Life Insurance Company were trying to find a solution to a tuberculosis problem which had been causing concern for a long time. Employees would occasionally report to the Dispensary complaining of typical symptoms of tuberculosis, although a satisfactory physical examination of the chest had been made a short time before. This happened in spite of the fact that our examining staff was made up of competent physicians, each one connected with hospital, clinic, or teaching institution, and some of them particularly trained in the diagnosis of diseases of the lungs. To complicate matters still more, we were seeing employees whose roentgenograms showed a lesion typical of pulmonary tuberculosis who had neither symptoms nor physical signs of pulmonary disease. With this evidence, we realized that even relatively large pulmonary lesions might not produce detectable signs or give any symp-

toms whatsoever. Incidentally, this was not as well known then as now.

We believed that for purposes of accurate diagnosis a routine X-ray examination of the chest would be ideal, but the technical problem of making the requisite 17,000 or more roentgenograms yearly was great and the question of expense was not ignored. Our problem was to find an accurate, rapid, economical way of selecting the proper cases for further X-ray study. It was decided to try fluoroscopy on a series of cases with the hope that this method of examination would fulfil the requirements. Consequently, in October, 1927, 100 individuals were examined physically, fluoroscopically and roentgenographically, and the results justified further trial.

In the first 7 months of this experiment 3,300 applicants for employment were examined, the examination consisting of the usual medical and personal history and physical and fluoroscopic examination. In this group we found 37 individuals whom we would have accepted after the physical examination, but who, after a fluoroscopic

* Read before the Child Hygiene Section of the American Public Health Association at the Sixty-third Annual Meeting in Pasadena, Calif., September 6, 1934.

examination, were classified as "abnormal chests," and then after X-ray examination were classified as having a lesion typical of pulmonary tuberculosis. We were convinced that we were on the right track and since that time have adhered to this method.

Our problem now divided itself naturally into two parts, the detection of pulmonary tuberculosis—(1) among applicants for employment and (2) among our Home Office employees.

From January, 1928, through December, 1933, 17,765 applicants for employment were examined, of whom about 95 per cent were girls and 5 per cent boys. The average age in this group was about 18 years. Among these applicants there were 244 persons whose roentgenograms showed a lesion typical of pulmonary tuberculosis (see Table I).

many of these applicants rejected because of chest lesions. We were able to follow closely 42 cases; the remaining 27 cases dropped from sight in spite of all efforts. The results were enlightening. Within the year we found by X-ray that 21, exactly one-half of the cases followed, had either a spread, or were complaining of symptoms denoting activity, or were developing abnormal physical signs, or already had been admitted to a sanatorium or hospital for treatment. Since starting this work we have been able to reexamine and advise 75 per cent of the applicants rejected because of the presence of pulmonary tuberculosis, most of whom were in need of immediate treatment.

The findings among Home Office employees are given in Tables II and III. Table II shows the decreasing number

TABLE I
INCIDENCE OF PULMONARY TUBERCULOSIS AND METHOD OF DETECTION
AMONG APPLICANTS FOR EMPLOYMENT
HOME OFFICE, METROPOLITAN LIFE INSURANCE COMPANY
1928-1933

Year	Number of Applicants	Cases of Pulmonary Tuberculosis and Method of Detection					
		Total		Suggestive History	Suggestive Physical Signs	Fluoroscopy Only	
		Number	Rate per 1,000 Applicants			Number	Per Cent of Total
1928-33	17,765	244	13.7	25	19	200	82
1928	4,405	169	15.7	9	7	53	77
1929	4,780	157	11.9	6	6	45	79
1930	3,105	36	11.6	3	1	32	89
1931	2,175	33	15.2	2	4	27	82
1932	2,134	32	15.0	2	0	30	94
1933	1,166	17	14.6	3	1	13	76

Because of the personal and public health aspects involved, we did not feel that our interest or responsibility ended with a refusal to employ these people. Consequently, we reexamined, advised, and did all we could to help in the proper disposition of these cases. During the first year we also secured additional and subsequent information upon

of new cases of tuberculosis detected yearly. The decrease is due largely to the detection and classification in 1928 and 1929 of the healed cases among the older employees, and also to the fact that we are not now employing persons with demonstrable tuberculous lesions. Table III shows decrease by years in the number of cases needing treatment.

TABLE II

CASES OF PULMONARY TUBERCULOSIS (ACTIVE, ACTIVITY QUESTIONABLE, APPARENTLY HEALED) DETECTED AMONG EMPLOYEES OF THE HOME OFFICE, METROPOLITAN LIFE INSURANCE COMPANY
1928-1933

Year	Number of Employees	Cases of Tuberculosis Diagnosed	Rate per 1,000 Employees
1928	11,530	106	9.2
1929	11,966	85	7.1
1930	12,468	71	5.7
1931	13,081	72	5.5
1932	13,582	59	4.3
1933	13,960	42	3.0

TABLE III

CASES OF ACTIVE PULMONARY TUBERCULOSIS AND METHOD OF DETECTION AMONG EMPLOYEES OF THE HOME OFFICE, METROPOLITAN LIFE INSURANCE COMPANY
1929-1933

Year	Total		Suggestive History or Physical Signs	Fluorosc- copy	Others (Routine X-ray Retake, etc.)
	Cases	Rate per 1,000 Employees			
1929	33	2.8	18	15	0
1930	29	2.3	17	12	0
1931	29	2.2	22	5	2
1932	33	2.4	20	8	5
1933	20	1.4	6	13	1

The results can be summarized by saying that we believe that we are not now employing persons with pulmonary tuberculosis and we are everlastingly alert to detect this disease in our Home Office employees at the earliest stage.

And, curiously, our endeavors have brought us face to face with another phase of the problem which is now causing some perplexity. For years we have been encountering individuals whose chest roentgenograms show evidence of a typical tuberculous lesion, who are asymptomatic and demonstrate no abnormal physical signs. Among the company employees we have advised and urged the younger ones and those whose lesions are shown to be unstable by X-ray examination to take treatment at the company sanatorium at Mount

McGregor, and have allowed the others to work under very close observation. So far, we believe we have made no mistake. An analysis of 141 cases diagnosed as tuberculous subsequent to a negative X-ray or negative fluoroscopic examination shows that significant pulmonary tuberculosis may develop in the late adolescent and adult, that it is possible to detect many of these cases at a stage before physical signs or symptoms can be elicited, that some of these cases follow an unsatisfactory course while others are cured without untoward incident at our sanatorium. It is not possible to foretell which case will react favorably and which unfavorably, so we believe that the safest method is to advise the younger members of such a group to take sanatorium

treatment under favorable circumstances, and to keep the older individuals under close medical observation.

After 7 years' experience with our present routine of chest examination, we believe that we have made real progress in handling our pulmonary tuberculosis problem. Realizing that a physical examination, no matter how painstakingly done, does not reveal ab-

normal signs in a large number of tuberculous cases, we have met this shortcoming by adding a routine fluoroscopic examination and a roentgenographic examination of cases selected by this method for further study. From the administrative standpoint, this method is rapid and economical; as checked by X-ray examination, it is accurate.

Our Front Window

WHILE we watched a drug clerk meticulously attach a label to a prescription the other day, we wondered how long this business of labeling merchandise had been going on. So we found out. At the Ever Ready Label Corporation in New York they know a lot of curious things about labels. One of them is that cattle were probably the first articles of commerce to be labeled—by brands, too!

Wooden labels for mummy cases came along about 1000 B.C. From the same period, on a bamboo container, this inscription has survived: "This is for swellings."

Of course we could go back further than that, if we wanted to. We now know about King Pepy I who flourished in 2750 B.C., and the big clay tablets of his reign which announced the ownership of various articles. And the

papyri of ancient Egypt carried tables of contents, and in 2698 B.C. Chinese potters were branding their wares in color.

One of those which interested us most—it is now at the Metropolitan Art Museum—said: "If you like my painting you may find me at the Bridge of Man-Chu." And then, too, we could talk for several minutes about Assyria and the heart-shaped stone tag with a hole through it. This bore the inscription: "Sheep belonging to the Shepherd Ludmahum."

Misbranding, we regret to report, arose with the increasing popularity of labels and in the Middle Ages an Elector of the Palatinate found it necessary to publish a warning that any innkeeper who sold ordinary wine labeled as Rudesheimer would be hanged.—*Am. Druggist*, Jan., 1935, pp. 14-16.

A Diphtheria Immunization Campaign in Austria*

GEORG PÖCH AND CHARLES N. LEACH

Director, Local Health Department, Eisenstadt, Austria; and International Health Division of The Rockefeller Foundation, New York, N. Y.

DURING the past 4 years Austria has suffered an unusually high incidence of diphtheria, but the case fatality rate has been extremely low. The province of Burgenland, which forms the eastern boundary of the Republic, has been particularly affected, as hospitals are few and far between, and the cost of antitoxin is in many cases prohibitive.†

In 1925 diphtheria preventive measures received a definite setback in Austria following 6 fatal accidents in Baden bei Wien.¹ The use of toxin-antitoxin was prohibited by government decree. In 1932, by authorization of the Austrian Superior Medical Council, the Bezirk Eisenstadt,‡ in the Province of Burgenland, where diphtheria was prevalent, and where no immunizations had been done, was set aside as a field where the newer methods of prophylaxis could be investigated. The primary object was to study the epidemiology of diphtheria and to demonstrate the harmlessness of formol-toxoid injections and their protective value.

The Bezirk Eisenstadt has a well organized health unit under the direction of a full-time health officer, and has served as a demonstration health unit since 1929. The staff of physicians and nurses is so organized as to facilitate follow-up work. As will be seen from Figure I, the diphtheria morbidity rate in the bezirk in 1932 was extremely high, 764 per 100,000 inhabitants. The case fatality was low, about 2.5 per cent, and there were very few severe cases. Austria as a whole shows a similar picture, with a considerable increase in the morbidity rate from 1930 to 1932, the highest since 1894.

The Burgenlanders are primarily agricultural, but their dwellings are almost entirely in closed villages. In these communities the housing conditions are in many instances as unhygienic as those in the most densely populated sections of Vienna; there is much overcrowding, and extreme poverty. The population of the Bezirk Eisenstadt according to the 1923 census was 42,010, concentrated almost entirely in 29 compact villages.

The high prevalence of diphtheria, with the disease occurring first in one village and then in another, has put a heavy financial burden on the communal governments and sickness insurance companies. There are no communicable disease hospitals in the district, and the cost of transporting the

* The studies and observations herein reported were conducted with the support and under the auspices of the International Health Division of The Rockefeller Foundation. This investigation was made possible through the consent and approval of the Volksgesundheitsamt of the Austrian Ministry of Social Welfare.

† Antitoxin retails at Sch. 3.80 (\$.70) per 1,000 unit lots. In quantities of 10,000 units it costs Sch. 35.00 (\$ 6.48).

‡ The bezirk corresponds to the American county.

FIGURE I—Comparison of the diphtheria morbidity rate for the Bezirk Eisenstadt with the rate for the Province of Burgenland and rates for Austria, Hungary, Czechoslovakia, and Germany, during the period 1922–1933

sick to those in neighboring bezirks has been considerable.

Since 70 per cent of all cases of diphtheria were being reported among chil-

dren 2 to 8 years of age, inclusive, it was decided to concentrate on this group with our program of immunization. The following plan was adopted:

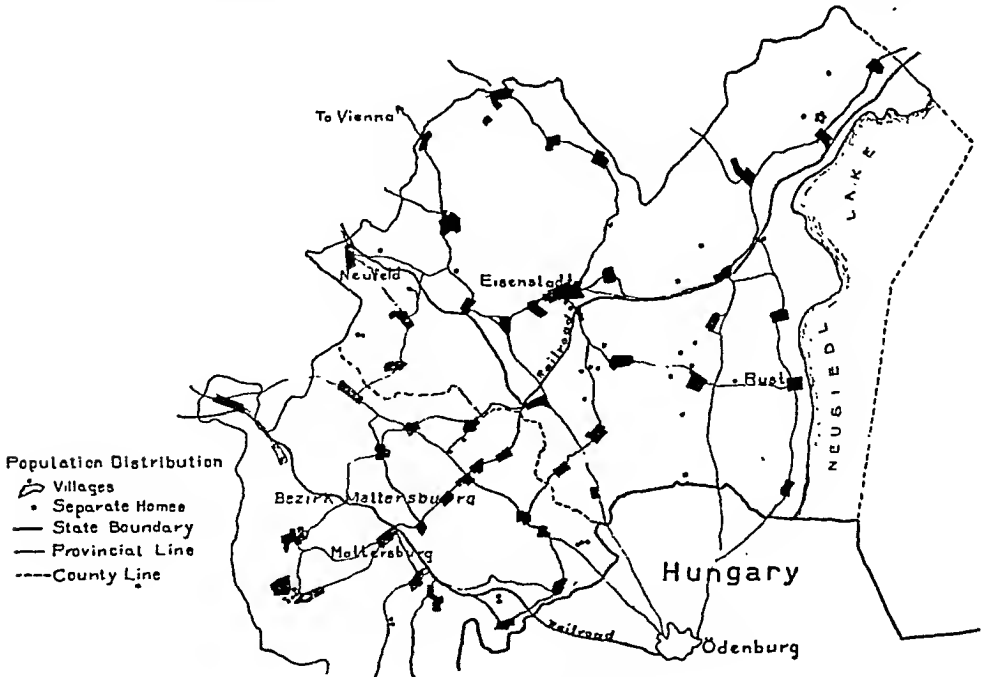

FIGURE II—Bezirk Eisenstadt

1. Perform Schick tests on, and take nose and throat cultures from, as many children as possible in the age group 2 to 8 years inclusive.

2. Read Schick tests 4 days later and administer 0.5 c.c. of formol-toxoid (8 fl. units) to each alternate Schick positive child, the remaining Schick positive children to be left as a control group.

3. Administer 1.0 c.c. of formol-toxoid 11 to 14 days after the first injection.

4. Administer 1.5 c.c. of formol-toxoid 11 to 14 days after the second injection.

5. Make virulence tests on all diphtheria cultures obtained from carriers.

6. Perform second Schick tests on as many immunized children as possible.

7. Take blood samples (5.0 c.c.) from a certain number of children in each village at the time of the second Schick test, and titrate the serum for antitoxin content as a parallel to the Schick test.

A card index was prepared including every child in the bezirk between 2 and 8 years of age, of whom there were 5,173. Of this number 4,879 appeared for the preliminary examination. Later, 4,809 were present for the Schick reading, of whom 3,096 were found to be positive. Of the Schick positives 1,746, or 56.4 per cent, were given 3 injections (3 c.c. total) of formol-toxoid. Of 2,006 children who received the first injection 1,746, or 87.0 per cent, completed the series. This high percentage was made possible through the excellent collaboration of the population and the local health authorities. The percentage of children receiving 3

FIGURE III—Percentage of Schick positive children, by ages, among a total of 4,809 tested

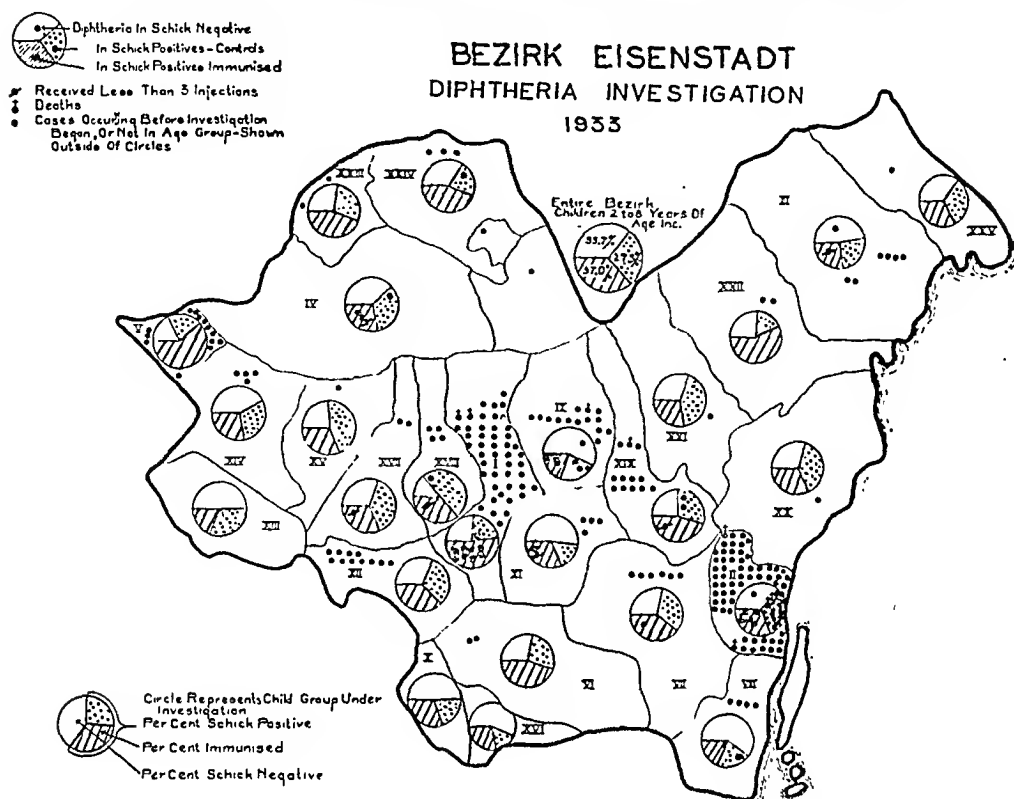

injections is generally much lower, and the efficiency of the 3 injection method is thus being markedly diminished. The campaign was inaugurated in May, 1933, and ended in August of the same year.

The toxin used for the Schick test is a product of the State Serum Institute in Vienna and complies with the international standard.² The immunizing material was formol-toxoid (8 fl. units), produced by the State Serum Institute and was supplied gratis. The formol-toxoid was injected subcutaneously over

Second Schick tests were done on 596 children in 8 villages from 10 weeks to 7 months after the third injection of

formol-toxoid. Of these, 44, or 12.6 per cent, remained Schick positive, and 552, or 87.4 per cent, were Schick negative after 3 injections.

Blood samples were taken from 213 children at the time of the second Schick test. The results of antitoxin titration as compared with Schick results will be reported later.

Complete results from the carrier survey are as yet not available. Of the 9,237 nose and throat smears examined, 124 gave positive results; and of these, 21 proved to be virulent on animal tests.

In each village every practising physician was furnished with a list of children in his community, showing results of Schick tests, those immunized, and results of second Schick tests on the latter. This served to stimulate their interest and assisted greatly in the reporting and follow-up of new cases.

It is approximately a year since the campaign was inaugurated, and it is interesting to note the results of immunization with a formol-toxoid of low antigenic value after this length of time. Diphtheria has continued to be very prevalent. The spot maps show the occurrence of the disease, Figure IV from the beginning of the campaign in May, 1933, to the end of the year, and Figure V from January 1 to May 1, 1934.

The village of Rust (see Figure II), population 1,361, presents a particularly interesting situation. During the past 12 months 97 cases of diphtheria have occurred, of which 12, or 19.4 per cent, were in the group having 3 injections of formol-toxoid (3 c.c. total). Of the total immunized in the entire district, 29, or 1.66 per cent, contracted the disease. It is evident that, in the face of a severe epidemic, and in spite of the fact that 92.6 per cent of the children were rendered Schick negative by the 3 injections of formol-toxoid, the antigen used offered an inadequate means of protection. While 29 cases occurred among the "immunized" children, there were only 37 in the control group. All cases of diphtheria

occurring among the children who had received the 3 injections of antigen were very mild, while among the unimmunized children, 11 deaths were recorded, of which 4 were in the control group.

SUMMARY AND CONCLUSIONS

In a rural county of eastern Austria, with an unusually high incidence of diphtheria, 1,746 children 2 to 8 years of age inclusive, out of a total of 3,096 Schick positives, were given 3 injections of formol-toxoid (8 fl. units). During the year following the inauguration of the campaign, 29 cases of diphtheria occurred among those, and 4 among children giving a Schick negative reaction.

The antigen employed was apparently of too low potency to protect against diphtheria when used in the presence of an epidemic of unusual intensity. The severity of the disease was modified in those who had received 3 injections (3 c.c. total) of antigen.

Experiences With Sewage Farming in Southwest United States

Texas

V. M. EHLERS, F.A.P.H.A.

Chief Engineer, State Board of Health, Austin, Texas

CERTAINLY no more appropriate time than the present could be selected for discussing the conservation of water for irrigation, even water from sewage disposal plants, when in many sections of the country crops are suffering from drought. However, in some sections of Texas, droughts are of more or less intermittent occurrence, and part of the state is normally arid; hence, the question of placing sewage effluents on land for crop irrigation has long been of interest to Texas engineers who were searching for an economical method of disposing of a city's liquid wastes. One town has been employing land disposal for more than 20 years, another for 9 years, while still others have used the process for 7, 6, 4, and 2 years with fair results.

The disposal of sewage on land has come about gradually and naturally as streams became foul during minimum flow periods and land disposal was found to be feasible and economical. There are now 68 towns in Texas using land disposal as a secondary means of sewage disposal, and of these, 34 grow crops, and 2 use sub-surface irrigation. The chief concern of the sewage engi-

neer has been to dispose of the effluent so as to cause no nuisance, and the value of the waste water as an irrigant has later become apparent. There is a tendency at this time to give more consideration to this means of sewage disposal, as much from a desire to provide water for crop irrigation as to keep waste water out of streams. The two-fold value of the method adds interest to the problem but also makes the method of disposal more complicated and difficult of successful operation.

A résumé of the data collected by a recent survey of Texas cities reveals some interesting facts concerning this method of sewage treatment or disposal.

Some cities purchase their land, paying from \$25 to \$125 per acre, and operate the farm; others lease the city owned land to farmers who get the revenue for taking care of the sewage effluent, while still others donate the water to a farmer for his own land, supplying the effluent as the farmer needs it.

The crops most successfully grown on these sewage farms are the small grains, as maize, hegira, kaffir, and corn; the grasses, as sudan, rescue, Johnson grass, and cane; although other crops as cotton and alfalfa have been grown with profit. In addition, orchards of pecan, walnut, grape fruit, and oranges are

* Read at a Joint Session of the California Sewage Works Association and the Public Health Engineering Section of the American Public Health Association at the Sixty-third Annual Meeting in Pasadena, Calif., September 6, 1934.

profiting by sewage irrigation in some sections. Small truck crops irrigated with sewage have included beans, pumpkins, potatoes, peas, and asparagus; while a few cities dispose of their excess activated sludge in the growing of roses, tulips, and other flowers.

The number of acres used by towns ranges from 1 to 3,500, while the total number of acres at present being irrigated for crops in Texas is approximately 4,500. The town using only 1 acre of land employs sub-irrigation. The City of San Antonio has for 20 years discharged its sewage effluent into Lake Mitchell, a holding reservoir, thence to approximately 3,500 acres of land which is cultivated. The average city sewage farm, however, is about 20 acres.

The cost to cities of irrigating varies from nothing, where the effluent is donated to a farmer, to \$10 per m.g., assuming no returns on the crops. In many instances the value of the crops has more than paid for the expense of keeping the farm in good condition. Cities operating their own farms have shown a revenue per acre per year of \$25 to \$135.

The minimum number of gallons of effluent applied per acre per day is shown to be 4,500, the maximum, 150,000 gal., but in the latter case the soil is sandy, regularly loosened, has good sub-drainage, and the effluent is applied only at weekly intervals. This virtually means a minimum application of 4,500 gal. per acre per day and a maximum of 25,000 gal.

All towns employing land disposal give the sewage some preliminary treatment, usually sedimentation in plain or Imhoff tanks, while several apply filtered effluents although this secondary treatment is not necessary for successful operation. It so happens that a few towns installed filters and later decided to dispose of the effluent on land. About 20 towns use land dis-

posal constantly, while some 48 depend on land disposal only intermittently, as during low stages in the receiving stream or as irrigation water is needed by the coöperating farmer or farm manager.

Land disposal of sewage effluents depends for its successful use upon local conditions such as type of soil, the amount of effluent available, cost of land, climate, and other factors.

While the majority of the towns employing this process satisfactorily are located in the arid western part of the state, a few in the southern and eastern portions have used it also with success. Two towns reported the soil too heavy in that particular locality, while one found the salt content of the effluent so high as to impair the soil for successful cropping. Four industrial institutions have found land irrigation a successful method of disposing of wastes from packing houses, cheese factories, and milk plants. The average rate of application for industrial wastes has been found to vary from 5,000 gal. per acre per day up to as high as 15,000 gal., where ideal conditions have been present. Where the land has not been overdosed, no nuisances have been reported.

As a guide to our Texas municipalities and designing engineers interested in land disposal of sewage, we have made the following suggestions:

1. Irrigation, with sewage effluents, of vegetables eaten raw will not be permitted at this time.
2. All sewage effluents disposed of on land should have pre-treatment by sedimentation, or other method, to reduce settleable solids by at least 50 per cent.
3. The use of an earthen holding tank or reservoir facilitates application of the liquor but its use is advisable only when located far enough from occupied homes to prevent odor annoyance and where proper maintenance to prevent fly and mosquito breeding nuisances is assured.
4. Adjustment of chemical treatment to avoid injury to soil bacteria and removal of

all oils and greases is necessary. Acids and alkalis in the effluent are likely to ruin the fertility of the soil.

5. Care must be exercised in applying a sewage effluent to growing crops, in order to prevent ponding and water-logging of the land. The furrow irrigation is found to be more practical than the border method.

6. Sludge disposal can be successfully effected in some instances by means similar to those employed in broad irrigation.

7. Acreage required for broad irrigation will depend primarily on the soil, both top and sub-soil which must of necessity be porous, as sand, sandy loams, etc. A study of the absorptive capacities is requisite to determination of area required.

8. A study of the water requirements of all possible crops is under way. The amount of sewage conducive to the growth of one crop may be an "over dose" to another. If utilization of the effluent for crop irrigation is not anticipated, the study will of course

be confined to natural existing vegetation.

9. With few exceptions sewage should not be applied to the fields in quantities greater than that absorbed within a period of 30 minutes. Rotation and intervals of application will vary with absorptive characteristics of the soil and the frequency of plowing. Deep plowing (12") at intervals of 6 to 12 months is recommended. Frequency of shallow plowing will be determined by surface conditions and should be practised to the extent that top soil will dry out thoroughly. Ponding should be prevented at all times to eliminate potential nuisances.

10. If crops are to be planted, reserve acreage must be provided upon which effluent can be placed during rainy weather and when crops do not require additional moisture.

11. Rainfall, evaporation, and temperature are to be taken into consideration in determining the acreage requirements for land disposal.

Cancer

CANCER research is taking a new tack, according to Dr. William J. Mayo of the famous Mayo Clinic at Rochester, Minn. This he described as an individualistic study of cancer as it occurs in different types of people according to various conditions, sexes and social customs and chronic irritation previously.

In comparison with other diseases cancer was studied and attacked as a problem of mass disease. Now, however, search is directed at ascertaining why certain people are susceptible to cancer while a far greater number are immune to it under the same conditions.—*Am. Druggist*, Jan., 1935, p. 4.

Experiences With Sewage Farming in Southwest United States*

Arizona

F. C. ROBERTS, JR.

State Sanitary Engineer, State Board of Health, Phoenix, Ariz.

IN endeavoring to present to you the sewage farming situation in Arizona, there are many items which have to be omitted due to a lack of reliable information; but with the information available, the subject will be presented as thoroughly as time permits.

When first considering this subject, the city of Tucson was studied from every angle, then by incorporating some material from the city of Casa Grande, a more complete picture is obtained of the sewage farming situation in the southern part of the State of Arizona.

This portion of the United States is most arid; this climatic feature has a tremendous influence on farming conditions.

In presenting the picture of sewage farming the cities of Tucson and Casa Grande will be generally considered from the viewpoints of operation, economics, and public health.

SEWAGE FARMING IN TUCSON

In considering this situation it is necessary to give the following pertinent facts about this city:

Population according to the 1930 census	32,506
Average yearly precipitation	11.5"

Average temperature per year	66.0° F.
Average minimum temperature	49.9° F.
Lowest recorded temperature	12.0° F.
Average maximum temperature	82.0° F.
Highest recorded temperature	112° F.
Average sewage flow	2.5 m.g.d.
Average type of sewage is domestic, with small creamery waste	
Average water consumption (1922-1933 inclusive)	4.9 m.g.d.

The city has a separate sanitary sewerage system that concentrates at the northwest corner of the city. From here the sewage flows by gravity through a 30" concrete outfall line to an inverted siphon some 3.1 miles from the city. After passing through the siphon under the river, the sewage flows through a screening chamber, then into a sedimentation chamber, with a 30-45 minute retention period, then out onto the farm. The sludge from the sedimentation chambers is concentrated and automatically pumped into a battery of 5 uncovered sludge digestors, the overflow from the digestors running back into the sedimentation chambers.

The raw sewage as it reaches the screening chamber has a hydrogen sulphide content at times of approximately 6 p.p.m., which is not surprising in view of the fact that the inverted siphon has to be cleaned from time to time due to accumulations of solids. There are places of seeding along the outfall line that produce a septic influent to

* Read at a Joint Session of the California Sewage Works Association and the Public Health Engineering Section of the American Public Health Association at the Sixty-third Annual Meeting in Pasadena, Calif., September 6, 1934.

the plant. The nature of the plant with purely primary sedimentation does not improve the quality of the effluent, except to reduce the suspended and settleable solids in the amount of 79 and 95 per cent, respectively. The suspended solids average about 300 p.p.m. in the raw sewage.

The effluent as it discharges onto the farm, is therefore in a septic condition, and odors arising from the farm should not be charged to the farm, nor in the main to the uncovered condition of the digestors at the plant, but rather to the poor condition of the influent.

In the operation of the farm, there are objectionable odor conditions that arise from time to time, although recently there have been few objections by neighbors. These odor conditions may be kept to a minimum if the following precautions are observed in tilling the soil:

1. Pooling or standing of sewage in the furrows should be completely eliminated, either by plowing, cultivating, or other process.

2. Banks of ditches should not be allowed to become rank with growth so as to catch and retain the solids along the borders. This may be controlled by the use of chemicals, or by keeping the banks constantly spaded.

3. Cross-sections of irrigation ditches should be small with a maximum of depth and a minimum of width.

4. Choice of soil is an important item. A sandy loam is to be preferred to other type to preclude possibility of the soil "sealing itself off."

5. The city should operate the farm itself or have administrative power over the management to preclude the possibility of nuisance.

The city of Tucson has protected itself from odor complaints by the purchase of large tracts of land. At the present time the area of the farm comprises 1,360 acres of which they use 200 in summer to dispose of the $2\frac{1}{2}$ m.g.d., or 12,500 gal. per acre per day in the hot summer months with the high evaporation available; and 350 acres in winter to dispose of the same amount

of sewage, or 7,800 gal. per acre in the winter months.

It takes approximately 5 men, including the superintendent, to operate this farm and disposal plant adequately.

The crops that are grown in this particular climate with the yield per acre as accurately as the available information presents are:

1. Barley for hay and grain, 1 ton of threshed grain and $1\frac{1}{2}$ tons of hay per acre per crop

2. Corn for use as ensilage, $8\frac{1}{2}$ tons of ensilage per acre

3. Alfalfa for use as hay, 1 ton per acre per cutting, and 5 cuttings per year

4. Maize either as milo-maize, higuera, or federita, all used as fodder crops, 1 ton per acre

5. Sudan grass used for grazing (this practice has been discontinued)

6. Cotton, 1 bale per acre

According to a former farm superintendent, a yield of 25 to 30 per cent greater from sewage irrigated land would be expected than from other irrigated land in that particular locality. Due to the fact that this farm has not been completely leveled, the yield is approximately the same as that from adjacent farms.

A few of the economic features are presented below:

CAPITAL INVESTMENTS

Cost of the 1,360 acres for the farm	\$64,350
Cost of the disposal plant and accessories	82,600
Cost of various improvements to the farm itself	30,000
<hr/>	
Total cost of the system up to the present	\$176,950

Operational costs include all outlay, subtracting all income:

1927-1928	\$7,655.74
1928-1929	9,041.18
1929-1930	16,468.56
1930-1931	22,744.14
1931-1932	8,852.89
1932-1933	4,324.59
1933-1934	3,327.73

The years of high operational cost

were those in which ambitious programs were carried out. It has been discovered that if the farm is operated only as a means for disposing of the sewage, without attempting to produce record crops, or incidentally to compete with other farms, greater economy is effected. Crops raised are but incidental items, revenue from crops helping to offset operation expense. In addition, if this policy is carried out it does not place the city in the embarrassing position of trying to compete with private enterprise.

The public health aspects are roughly presented in the following sub-divisions:

1. Harvesting and pen-feeding, seemingly present little danger. The crops that are at present grown on this land are harvested so that they are exposed to a minimum of contamination. The hay that is cut is on a dry field. With the amount of curing and exposure to the elements it seems hardly possible that disease could arise from this source.

2. If cattle are grazed, an entirely different condition arises. To illustrate this point an example of a recent condition is submitted:

A herd of 45 cattle fattened on this farm were slaughtered and 23 were found to be infested with tapeworm (*Cysticercus bovis*), the larval stage of the tapeworm *Taenia saginata*. The cattle all bore different brands and were assumed therefore to have come from different ranges. Due to this fact, and also that this particular herd of cattle persisted in drinking effluent from the plant in preference to fresh water, it has been concluded that they were infested from this common origin.

With the exception of the draft animals grazed on this land and used by the city, it has been recommended that the practice of raising live stock on this farm be discontinued.

3. The danger from fly-borne disease is great from a farm of this kind

if the farm is not properly worked. The personnel must watch for and eliminate all places of fly breeding.

4. The danger of use of this type of broad irrigation to underground water supplies has not been thoroughly investigated, although no signs of pollution have been discovered. If the region were more populous, this might be a serious problem, but as the shallow ground water table is at a depth of at least 30', and domestic wells are located a considerable distance from the main body of the farm, it is not as important as it might be elsewhere.

SEWAGE FARMING IN CASA GRANDE

The city of Casa Grande will be compared from some viewpoints with Tucson.

The statistics necessary to obtain a picture of this community are:

Population according to the 1930 census	1,351
Average yearly precipitation	6.89"
Average yearly temperature	71.7° F.
Average minimum temperature	51.7° F.
Lowest recorded temperature	13.0° F.
Average maximum temperature	87.6° F.
Highest recorded temperature	122° F.
Average sewage flow per day	150,000 gal.
Type of sewage—domestic with small creamery wastes	
Average gross water consumption per day (1933)	238,000 gal.

There is a separate sewerage system that concentrates at the northwest corner of the city, where the sewage is treated with chlorine gas, and after treatment flows 6,300' northwest to the outfall, which is a 12" vitrified clay tile pipe.

At the point of outfall the sewage was at one time introduced into a septic tank, but due to the trouble caused by irrigation with septic sewage this was discontinued. For the past 3 years the raw sewage has been taken from the outfall and used for irrigation.

The chlorination of the sewage has been experimented with to the point that they may control odors at the

sewer farm if they dose at the rate of 6-7 p.p.m., although residual chlorine is not carried in the sewage to a man-hole 300' away from the point of chlorination. If the dosage of chlorine is increased to 10-11 p.p.m. the residual chlorine will be carried to the point of outfall.

In farming only 25 acres are required to dispose of the sewage, or 6,000 gal. per acre. The city owns 40 acres of this sandy loam, but have not been obliged to use more than the 25. The small acreage required is due principally to the control of odors through chlorination.

The only crop raised is cotton. The yield is usually 2 bales per acre, as compared to 1 bale per acre on the best adjacent farms.

The city does not farm this land itself, but leases it at a rate of \$90 for 3 years. The cost of chlorination is \$.50 per day, or \$183 per year, dosing at the rate of 6-7 p.p.m. Therefore, the cost to the city is \$153 per year plus supervision to dispose of the 150,000 gal. per day flow.

It takes but 1 man, furnished by the lessee, to take care of this amount of sewage on this 25 acre tract. The provision made in the city's contract is

that only those crops approved by the city government will be grown. The city therefore has an administrative power over the land.

CONCLUSION

In conclusion, it would seem that a combination of these two methods of sewage farming would be satisfactory in this climate providing that industrial wastes do not complicate the problem. With the ordinary domestic wastes, the system of prechlorination with a long contact period, to aid in sterilization, and to enable the sewage to reach the land in a fresh condition, coupled with screening and primary sedimentation to relieve the land of some of the load placed on it, would prove economical and satisfactory from every viewpoint, in the system of sewage farming as developed by these two cities.

NOTE: Appreciation is extended to the following individuals in their coöperation and efforts in discovering information on this subject:

George W. Marx, Sanitary Engineer, City of Tucson

R. C. Butler, City Manager, City of Tucson

C. E. Pecquignot, Auditor, City of Tucson

M. E. Watson, Farm Superintendent, 1930-1932, City of Tucson

Mr. Norman, City Engineer, City of Casa Grande

Tribute to Bailey K. Ashford

FROM Puerto Rico comes word of an affectionate tribute paid to the memory of Dr. Bailey K. Ashford, whose autobiography, *A Soldier in Science*, was published recently by Morrow.

In the hall of the School of Tropical Medicine, at San Juan, stands the bust of Dr. Ashford. Since his death a few weeks ago the early morning arrivals at the school have found the statue banked with flowers, many in strange

little native jars. A watchman was appointed to see who the donors were. In the middle of the night several Puerto Rican women, dressed in shabby black and heavily veiled, stole in, their arms filled with flowers. It was evident that they were poor people who had walked many miles from the heart of the hills to pay a last tribute to the doctor who had saved them or their children from the scourge of hookworm. —*N.Y. Times Book Rev.*, Dec. 30, 1934.

Experience With Sewage Farming in Southwest United States*

California

E. A. REINKE

*Senior Sanitary Engineer, Bureau of Sanitary Engineering,
State Department of Public Health, Berkeley, Calif.*

IRRIGATION of crops with sewage has been practised in California for many years. Pasadena's sewer farm was purchased in 1887 and is probably the oldest in the state.

Early methods of handling sewage were crude. Few treatment plants were in use and there was little or no restriction on crops raised. The tendency then, as now, was to derive the greatest possible revenue from the farm, and regard for sewage disposal was secondary. It naturally followed that dissatisfaction arose; neighbors complained of odors; flooding of adjoining property; and fly and mosquito breeding. In 1900 to 1910, many septic tanks were constructed, hoping to overcome the objections; but experience with them was disappointing. Imhoff tanks came on shortly after and gave some improvement. In recent years, both Imhoff tanks and separate sludge digestion plants have been used for preliminary treatment and the trend has been to adopt trickling filters and activated sludge plants for oxidation works, prior to irrigation.

There was a steady increase in use

of sewage for irrigation during the 30 year period from 1890 to 1920. The peak was reached about 1923 when some 70 municipalities disposed of all or part of their sewage by irrigation of crops. Accurate data are not available for the period before 1920, but since that year, 15 places have started irrigation with sewage and 30 others have abandoned the practice. Those abandoning sewage farming have, in the majority of cases, gone into joint outfall sewers, spread the sewage on land without cropping, or constructed new disposal works. At the present time, sewage from 53 municipalities is being disposed of by irrigation of cultivated crops, from 9 others by irrigation of wild crops, and from another 28 on land with no crops.

Thus 90 out of a total of 310 municipalities in California having sewer systems, now have land disposal.

A survey of use of sewage for irrigation in California was made by the Bureau of Sanitary Engineering in 1933. At that time 62 cities reported use of sewage on land, and 46 went in for some kind of cropping, watering a total of 4,050 acres. Of this, 3,628 acres were under cultivation, the remainder being wild grass. The acreage of various crops irrigated with sewage effluent included 340 acres of vegetables (all of

* Read at a Joint Session of the California Sewage Works Association and the Public Health Engineering Section of the American Public Health Association at the Sixty-third Annual Meeting in Pasadena, Calif., September 6, 1934.

varieties that are eaten cooked); 150 acres of dry beans, 63 acres of tomatoes, and 1,660 acres of fruit trees and vineyard. The remaining 1,617 acres were planted to alfalfa, fodder crops, sugar beets, hops and cotton.

In 1918 the California State Board of Health adopted regulations concerning use of sewage effluents for irrigation, which prohibited irrigation of berries and salad vegetables; permitted irrigation of vegetables harvested in the dry state; and permitted, under restrictions, such uses as (1) for garden truck if not watered 1 month before harvesting; (2) orchards, if windfalls were not gathered for human consumption; (3) melons if raised on hills above the water; and (4) fodder crops if milk cows were excluded from the fields.

Under the regulations, health officials were obviously required to supervise the growers and the regulations proved unsatisfactory.

In recent years, with increasing population, shrinkage of water supplies and improved methods of sewage treatment, several groups urged wider use of sewage effluents for irrigation which could not be done under the then existing regulations.

Under all the circumstances a revision of the regulations seemed advisable, and after a series of conferences with health officers and sewage disposal experts, new regulations were decided upon and adopted in May, 1933, based on classification of sewage effluents as well as on crops to be irrigated.

The aim was to minimize the supervision of the growers by health departments and, instead, to concentrate efforts on operation of the sewage treatment plants and the character of effluent produced.

In brief, the present rules forbid the use of raw sewage and raw or undigested sludge for irrigation of growing crops; make no restrictions on use of well oxidized, highly disinfected effluents; and permit the use of settled and undisinfected effluents on nursery and fodder crops, cotton and sugar beets but not on vegetables, berries and low-growing fruits.

Since sewage irrigation is considered an integral part of sewage disposal, the intention is that its regulation in California be handled under the permit features of the Public Health Act. This Act governs all forms of sewage disposal.

Treatment and Disposal of Sewage in the National Parks*

H. B. HOMMON, F.A.P.H.A.

Sanitary Engineer, U.S. Public Health Service, in Charge Sanitation in National Parks in the Western Division of the National Park Service, San Francisco, Calif.

SINCE 1922, sanitary engineers of the U. S. Public Health Service have been detailed to the National Park Service to assist superintendents of national parks, custodians of national monuments, and engineers of the Park Service on problems of sanitation in the parks and at monuments. The work of the sanitary engineers has included surveys and reports of investigations of water supplies, sewerage and sewage disposal, garbage disposal, swimming pools, mosquito control, and general inspections of all places handling and serving food products. In addition, plans have been prepared for water supply systems, sewage treatment plants, and garbage incinerators.

The sewage treatment plants discussed in this paper have been constructed in the parks in the Western Division of the National Park Service. In this division, which includes the National Parks west of the Mississippi River, except Hot Springs National Park, Arkansas, there are 19 parks located as follows: 1 in Alaska, 1 in Arizona, 4 in California, 2 in Colorado, 1 in the Hawaiian Islands, 1 in Montana, 1 in New Mexico, 1 in Oregon,

1 in Oklahoma, 1 in South Dakota, 2 in Utah, 1 in Washington, and 2 in Wyoming. All, except Hawaii, are located in sections or at elevations where there are more or less severe winters. Some are practically inaccessible in winter, others are visited by parties on snow shoes or skis, and 10, which include Carlsbad Caverns, General Grant, Grand Canyon (South Rim), Hawaii, Mount Rainier, Platt, Rocky Mountain, Sequoia, Yosemite, and Zion, are open to tourists by train or automobile throughout the year.

In 1933, the number of visitors was 2,013,024. The maximum number visiting one park was 296,088 at Yosemite, and the smallest, 368, at Mount McKinley. The parks having over 100,000 visitors were: Yosemite, 296,088; Rocky Mountain, 291,934; Hawaii, 237,690; Platt, 220,606; Mount Rainier, 170,104; Yellowstone, 161,938; Sequoia, 126,464; and Grand Canyon, 105,475. There is in addition to the visitors a permanent population which varies from a few in the smaller and less patronized parks to approximately 1,500 in Yellowstone.

The accommodations for visitors in the parks are hotels, lodges, house-keeping cabins, and automobile camp grounds, and for the permanent population residences and dormitories. The locations of these accommodations in

* Read at a Joint Session of the California Sewage Works Association and the Public Health Engineering Section of the American Public Health Association at the Sixty-third Annual Meeting in Pasadena, Calif., September 6, 1934.

the various parks vary widely. At the South Rim of the Grand Canyon practically all the visitors and employees live in one area, whereas in Yellowstone there is 1 area with all the accommodations listed above, 4 with all the accommodations except residences, 2 other places with lodges, housekeeping cabins, and large camp grounds, and several other smaller areas having automobile camps. The maximum number of people in one area in a park was 23,000 in Yosemite Valley on July 4, 1932. In Yellowstone there are 6 areas where the total population will vary from 100 to 2,500 people, and other places, mostly automobile camps, where the number of tourists will range from 25 to 100. In Yosemite Valley there were at one time 9,000 visitors living in tents in tourist camps, and in Yellowstone 800 in each of 2 camps.

There are in the western parks, 65 areas having for visitors extensive accommodations which are generally grouped together and served by a common water supply system, sewerage system and disposal plant, garbage incinerator, and other public utilities.

There have been constructed 52 sewage treatment plants since 1922. In designing these plants the important considerations were: (1) protection of streams against contamination and in one park reclamation of sewage for industrial purposes; (2) prevention of odor nuisances; and (3) maintaining architectural and landscape values. The treatment plants constructed include (a) activated sludge, rapid sand filter and disinfection; (b) activated sludge and disinfection; (c) settling tanks and disinfection; (d) settling tanks and spraying systems which distribute settled sewage, with and without disinfection, over natural ground surfaces, usually hillsides of porous material; (e) settling tanks and sub-surface galleries with concrete, wood, or metal walls and covers; (f) settling tank and glass-

covered sand filter; (g) settling tanks and open trenches; and (h) settling tanks, broad irrigation, ponds and disinfection. Following are descriptions of a representative plant of each of the types listed above.

ACTIVATED SLUDGE, RAPID SAND FILTER AND DISINFECTION

The cost of hauling water to the South Rim of the Grand Canyon National Park in tank cars and delivering it in service lines, prior to 1932 was \$3.07 per 1,000 gallons and approximately \$2.50 for pumping and delivery since that date. In order to reduce the volume of water hauled, a pressure sand filter was added in 1913 to an existing sewage treatment plant, consisting of septic tank and contact filter, to produce an effluent which could be used in place of fresh water for irrigation of lawns and making steam. For a few years following 1913 the effluent was apparently satisfactory for the purposes noted, but with an increasing volume of sewage the plant became badly overloaded, a serious odor nuisance developed, and the effluent could not be used on lawns because of the odors, or in boilers due to foaming.

It was decided in 1926 to build a new sewage treatment plant to produce an effluent which could be used for industrial purposes and be distributed in a separate piping system properly protected against cross-connections, without being a serious health hazard to the visitors and people living at the South Rim.

A treatment plant consisting of settling tank, slow sand filters, and disinfection seemed to have the most inherent advantages from the standpoint of high removal of bacteria and quality of effluent in general, and low cost of operation and maintenance, but it was impracticable to build this type of plant on account of the high cost of sand delivered to the South Rim. The

FIGURE I—Sewage Treatment Plant, Grand Canyon National Park

treatment plant designed included activated sludge, rapid sand filters, and disinfection.^{1, 2} The local conditions, other than those pertaining to the industrial uses of the reclaimed sewage, which had to be given consideration in the design of the treatment plant, were the variations in the temperature of the raw sewage, from 92° F. in summer to 72° F. in winter, and the treatment of the laundry wastes, which constitute approximately 10 per cent of the total volume. Figure I shows a general view of the treatment plant.

The available data indicated that the maximum volume of sewage produced at the Canyon during 1926 was 100,000 gal. per day, and the treatment plant was designed to treat 200,000 gal. The following devices were included in the plant:

Screen—The screen is 3' wide by 3' deep and has $\frac{3}{8}$ " by 2" rectangular iron bars spaced $2\frac{3}{8}$ " on centers.

Pre-settling tank—This tank is 16' by 8', with an effective depth of 5' to the top of the two hoppers which are 4' deep. The theoretical detention period is 30 minutes for a maximum

volume of 200,000 gal. of sewage per day.

Diversion chamber—This is a small tank located on the pipe line from the pre-settling tank to the aeration tanks. It receives the activated sludge returned from the clarifier to the aeration tanks and can be used for by-passing the sewage around the plant.

Aeration tanks—There are two of these tanks, each 42' by 8' by 10' deep below the water level. They were designed for an average aeration period of 6 hours.

In each tank there are two continuous concrete channels each 42' long and having at the top porous plates which rest on T-irons across the channels and in recesses along the sides of the channels, and which are held in place by cement grout. There are concrete ridges between the channels. The air is pumped through 4" pipes to one end of the channels, and at the opposite end there are 4" outlet pipes which permit flushing of the channels and cleaning the under surfaces of the porous plates with water or steam. The tanks were designed so that they can

be operated in series or separately.

Clarifier—This tank is 16' square with an effective depth of 11½'. It has a settling rate of practically 800 gal. per sq. ft. per day, and a theoretical detention period of 2 hours when sewage is flowing through at a rate of 200,000 gal. per 24 hours. The influent enters the tank through 4 openings spaced equidistant along one side and 1' below the water surface, and the effluent flows over a brass weir the full width of the tank. There are inlet and outlet baffles extending 3' below the water level. The activated sludge moved by the scrapers of the clarifier to the center of the tank is returned to the aeration tanks by an air lift.

Coagulation tank—This tank, originally designed as a coagulation basin to be used in connection with operation of the rapid sand filter, is 16' by 4' by 10' deep. Up to the present time, the filters have operated satisfactorily

without the use of coagulants and this tank has been used as a secondary settling tank.

Rapid sand filters—There are 2 of these filters each having an area of 77 sq. ft. The wash-water troughs are of concrete and the underdrainage consists of 12" headers with 1¼" cast iron laterals having ¼" holes bored on 3" centers. Each filter has 20" of graded gravel and 32" of sand with an effective size of 0.40 mm. and a uniformity coefficient of 1.6. Reclaimed sewage, disinfected, is used for washing the filters.

Disinfecting equipment—Duplicate semi-automatic chlorine machines are used for disinfecting the effluent from the sand filters.

Blowers—Two blowers each with a capacity of 225 cu. ft. of free air per minute against 6½ lb. pressure per sq. in. at an altitude of 6,500', supply the aeration tanks and air lift with air.

Note R—Raw sewage.

C—Effluent clarifier.

C.W.—Clear well.

P. H.—Tap at make-up tank in power house.

Wash-water storage tank—This tank, which is used to store the wash water from the filters, is 25' long by 16' wide and 4½' deep below the overflow. A small centrifugal pump returns the wash water to the pre-settling tank.

Pumping equipment—The final effluent from the plant is pumped through 1½ miles of 4" pipe to a 200,000 gal. elevated tank by two 3-stage centrifugal pumps.

In Tables I, II, and III are given, respectively, the *B. coli* density in the reclaimed sewage for the years 1929 to 1933 inclusive, the monthly averages of chemical analyses, and data pertaining to the operation of the treatment plant for 1933 and up to August, 1934.

Handling reclaimed sewage—All the pipe lines carrying reclaimed sewage are enclosed in vitrified pipe and all pipes in buildings or above ground are painted red, and over every service outlet there is a sign warning against drinking the water. The tank in which the reclaimed sewage is stored is 125' lower than the tank used for domestic water. Accurate maps of the 2 water systems are kept up to date. Beginning in October this year a dye solution strong enough to give a color to the reclaimed sewage will be added once

FIGURE II—Sewage Treatment Plant, Yosemite National Park

a month to the effluent at the treatment plant.

Uses of reclaimed sewage—The reclaimed sewage is used in locomotive boilers, boilers for heating purposes, for watering lawns and flowers at the El Tovar Hotel, for flushing toilets in public comfort stations, washing automobiles, cooling water in jackets of Diesel engines, and in pipes used for drying garbage in an incinerator.

Cost of reclaiming sewage—The cost of operating the treatment plant, exclusive of interest and depreciation, but including pumping the reclaimed sewage to the storage tank, averages approximately \$0.38 per 1,000 gal.

ACTIVATED SLUDGE AND DISINFECTION

In 1930 there was constructed in Yosemite Valley, in Yosemite National Park, an activated sludge plant^{3, 4} to replace an Imhoff tank and natural sand filters which were badly overloaded and producing offensive odors. Yosemite Valley, at the only place where a new sewage treatment plant could be located, is approximately 1 mile in width with vertical walls about 3,000' in height, and there are two

highways, one on each side of the river which flows through the valley. On account of the odor nuisance and bad appearance of the old treatment plant, and the unfavorable topography of the floor of the valley, with regard to suitable sites for a new plant, local sentiment in the valley was doubtful that any type of treatment plant would operate without some kind of nuisance. The stringent requirements which the new plant had to meet were (a) that there would be no odors, (b) that the plant could not be seen from the highways on the floor of the valley or on slopes leading out of the valley, (c) that there would be no noise, (d) that the Merced River, which is used as a source of domestic water supply, would not be contaminated, and (e) that fish in the river would not be killed by chlorine in the effluent.

The treatment plant was designed for a maximum of 1,200,000 gal. of sewage daily, which was approximately twice the maximum flow up to 1930. Practically all of the sewage is pumped to the plant at a rate of 850 gal. per minute, which, while the pumps are operating, gives a rate of flow of 1,200,000 gal.

TABLE III

† Average rates; maximum rates are approximately twice the averages.

through the plant. The general layout of the plant is shown in Figure II.

The plant has the following treatment devices and equipment:

Coarse screens — The screen chamber, which is 7½' by 5' by 2' deep below the outlet, has two bar screens, one with 2" and the other with 3" openings. The screens were designed primarily to remove coarse material which might clog the 12" siphon which begins at the screen chamber and extends under the river to the pre-settling tank.

Pre-settling tank — This tank is 40' by 10' by 16' deep to the bottom of the hoppers, and has a concrete cover. The theoretical detention period is 45 minutes when treating 850 gal. per minute, the capacity of the pump normally used to lift the sewage to the gravity line to the treatment plant. There is a baffle at the inlet but only a skimming weir at the outlet. The sludge is drawn from the hoppers to the thickening tank daily during the period of maximum travel to the park.

Aeration tanks — There are 4 aeration tanks of the Manchester type, each 50' by 18½' and 12' effective depth. There are in each tank, two rows of porous

plates set over continuous channels extending the length of the tanks. The plates were set in recesses along the sides of the channels and on flat aluminum bars across the channels. Cement grout was used to hold the plates in place and make airtight joints. Air is applied at one end of the channels and at the opposite ends there are outlets for flushing them and washing the under surfaces of the plates. Tanks 1 and 2 are arranged for operation as single units, in series or in parallel, and tanks

3 and 4 in series with 1 and 2. The tanks were designed for a theoretical aeration period of $5\frac{1}{2}$ hours with 20 per cent activated sludge.

Final clarifiers—The two clarifiers, each 28' square at the top and with circular bottoms, have 11' and 10' effective depths, respectively, and are operated in series. Each tank was designed for a settling rate of 1,600 gal. sewage per sq. ft. per day and has an inlet baffle $5\frac{1}{2}'$ deep. Sludge is drawn by air lifts from the first unit to the

FIGURE III—Yosemite National Park Sewage Treatment Plant Showing Machinery Room, Laboratory and Office Building and Glass Covered Sludge Bed

aeration tanks and from the second unit to the pre-settling tank. Liquid chlorine is applied to the influent to the second clarifier by full automatic chlorinators in duplicate.

Thickening tank—This tank is 12' by 13' by 13' deep to the hopper bottom. Sludge is discharged into this tank by gravity from the pre-settling tank and the first clarifier. The concentrated sludge is pumped to the digestion tanks and the decanted liquor to the pre-settling tank.

Digestion tanks—There are 4 covered sludge digestion tanks, 3 of which are 28' by 12' by 18½' deep to the bottom of the hoppers, and the fourth, 13' by 12' by 18½'. There are concrete domes for collecting gas, coils around the walls for heating the sludge, and a pump for delivering sludge to the tanks and for circulating the sludge. Digested sludge flows by gravity to the sludge drying bed.

Sludge drying beds—The glass covered sludge drying bed is divided into 5 sections, each 15' by 40' and has

1' of river sand with underdrainage connected to a pipe line leading to a pump sump.

Drainage sump—The waste liquors from the digestion and thickening tank, drainage from sludge beds, the wastes from laboratory and toilets, and all other liquid wastes from the plant, other than the disinfected effluent, are discharged into the drainage sump and pumped to the pre-settling tank.

Blowers—There are two centrifugal blowers, each with a capacity of 425 cu. ft. free air per minute against a head of 7 lb. at an elevation of 3,000'.

Operation of treatment plant—The plant is under the direct supervision of two operators between 8 A.M. and 2 A.M., with no one at the plant from 2 A.M. to 8 A.M. In addition to operating the plant, the operators inspect and keep in working order the ventilating apparatus at the Wawona Tunnel, and one of the operators makes the chemical analyses of sewage and bacteriological analyses of samples from the effluent of the plant, and water and

milk collected at various places in the park. Three samples of the effluent and 3 from the Merced River above and below the outlet of the plant are shipped to the U. S. Public Health Service Laboratory in San Francisco each week for bacteriological analysis. The treatment plant has been in continuous operation since August, 1931, and except for bulking of sludge in the aeration tanks at infrequent intervals, and minor troubles with the mechanical equipment, it has operated in a highly satisfactory manner. Figure III shows the laboratory and office building and glass covered sludge bed. Table IV gives the density of *B. coli* in the effluent of the treatment plant and in the Merced River above and below the outlet from the plant to the river.

On account of the many duties each operator has to perform at the treatment plant during his shift, it is necessary to limit the chemical analyses to those essential to the operation of the plant and to a knowledge of the character of the effluent discharged to the river. Table V gives operating data and the chemical analyses, except the suspended matter in the raw sewage which is determined only occasionally in composite samples collected on Sunday, which is the day of the week ordinarily with the heaviest travel to the park. The suspended matter in the sewage produced on Sundays averages between 100 and 125 p.p.m.

SETTLING TANKS AND DISINFECTION

Settling tanks with disinfection of the effluent, have been used for treating sewage at places in the parks where large rivers or lakes, which are not used as sources of domestic water supplies, are available for receiving the sewage. This type of plant is used at 7 places in Yellowstone Park where there are large hotels, lodges, and camp grounds. The

design of the settling tank used is shown in Figure V.

A uniform amount of chlorine, which is sufficient to disinfect the sewage at the maximum rate of flow, is added continuously to the effluent of a settling tank as it is discharged through vitrified pipe to the bottom of a contact tank which has a detention period of approximately 15 minutes at the time of maximum flow of sewage through the tank.

An inspector visits these plants daily to test the effluent for free chlorine and adjust the chlorine dosage. In adjusting the flow of chlorine to the maximum rate of flow of sewage, there is a fairly high chlorine residual during the night, but it has never had any effect on fish in the streams receiving the sewage. An attempt is made to maintain a chlorine residual of not less than 0.5 p.p.m. at all times.

In the fall of the year all the sludge is either drawn off from the tanks by gravity to prepared beds, or it is pumped out by portable gas-engine-driven diaphragm pumps and the tanks emptied and cleaned.

SETTLING TANKS AND SPRAYING SYSTEMS

In many of the national parks there are hotels, lodges, and tourist camps located in places, usually in the mountains, where the topography and other local conditions are unfavorable for the location, construction, and operation of the commoner types of sewage treatment or disposal plants, and where it is much less expensive and often more satisfactory in many ways to treat the sewage in settling tanks and spray the effluent, disinfected when advisable, over natural ground surfaces, usually hill-sides of porous material and covered with vegetation. This method of sewage disposal is generally used at areas

Note: Figures in table represent averages of daily records.

which are open to visitors only during the warmer seasons, and when there is little rainfall. There are 10 of these plants in the parks, with disinfection of the effluent at 3. Typical examples of this type of treatment plant are at Giant Forest and Lodgepole Camp in Sequoia National Park.

At Giant Forest, with a population of approximately 1,000 during the summer, the sewage is treated in a settling tank and the effluent applied by a siphon to sprays which are set in a pipe line approximately 800' long and operate under a head of approximately 50'. Below the sprays there is a heavy growth of trees and shrubbery and the soil for a depth of 2' is porous. The spraying system is located where the drainage area above is small and where the nearest stream below is approximately 1 mile away. The loose material and the vegetation absorb practically all of the effluent and no sewage has ever been found flowing over the ground at a distance of more than 500' below the sprays. This plant has been operated during the summer and fall months for 7 years. There is a slight odor of fresh sewage at the settling tank and where the sewage is sprayed over the hillside, but it cannot be detected 100' from the disposal plant. The absence of an odor nuisance at this and at most of the plants is due no doubt to the fact that the sewage is unusually fresh when it reaches them and that there is little decomposition in the settling tanks.

At the Lodgepole Camp, the sewage from an automobile tourist camp with a population of approximately 300, and a government utility area with 25 employees, is treated in a settling tank and the effluent, disinfected with chlorine, is applied by alternating siphons to sprays set on 2 separate pipe lines each 300' long and approximately 15' below the siphons. There

are trees and shrubbery below the sprays and the soil is sandy and loose. The effluent is disinfected to protect a stream which receives drainage from the area where the sewage is sprayed.

The areas used for the spraying systems at the different plants are selected where there is little drainage above and where the sewage will be sprayed over ground having no well defined depressions or channels. Whenever the sewage begins to flow in channels the adjacent sprays are closed and the ground is allowed to dry, and the soil raked. The design of the spraying system is shown in Figure IV.

SETTLING TANKS AND SUBSURFACE GALLERIES

In many areas where there are accommodations for a comparatively small number of visitors and where it is advisable for various reasons to have the sewage disposal system entirely below the surface of the ground, settling tanks and subsurface galleries are used. In these areas careful investigations are made to find suitable porous material, such as gravel or coarse sand.

The settling tanks, which are used from 4 to 6 months in the year, are cleaned each fall. These are designed for a capacity equal to the largest volume of sewage produced daily, with approximately an additional one-third capacity for storage of sludge. All the settling tanks which have been constructed have been designed on the above basis, and all of them are cleaned once a year. The filter galleries are open at the bottom and the covers consist of either concrete, redwood, or half-round corrugated galvanized iron. The half-round culvert pipe can be obtained in diameters ranging from 8" to 86". The length and width of gallery used in any particular case depends on the volume of sewage treated and the character of the subsoil. A typical disposal

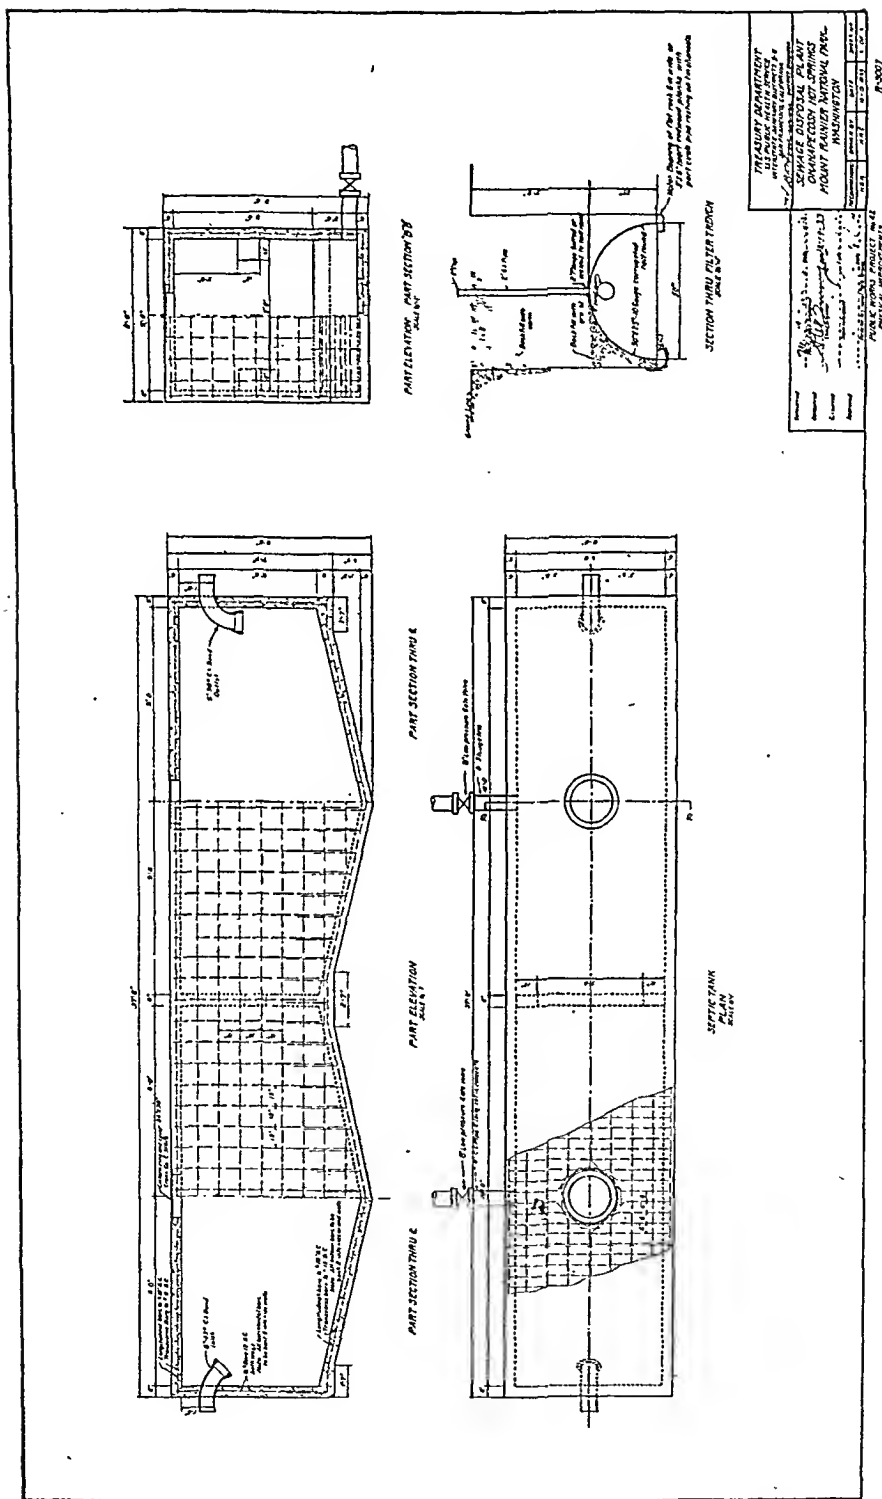

FIGURE V—Settling Tank and Sub-surface Gallery

plant of this type was constructed at Zion National Park to take care of the sewage from the headquarters area, housekeeping cabins, and automobile camp. In this area the only available site for a disposal plant is near the cabins, camp, and grounds used by visitors, and it was not advisable to have a sewage disposal plant above the ground. A design of a typical settling tank and subsurface gallery is shown in Figure V.

The effluent from the tank is piped to a diversion box from which it is discharged into 3 subsurface galleries each 100' in length and 5' in diameter. The subsoil is loose gravel and rock. The tank is covered with 2' of earth and the galleries are 5' below the surface.

There are 14 disposal plants of this type in the parks and all of them are operating satisfactorily. The main considerations which govern the successful operation of this type of plant are adequate storage for sludge and low settling rate in the settling tanks, porous subsoil, and sufficient area in the galleries.

SETTLING TANKS AND GLASS COVERED SAND FILTER

On account of unfavorable local conditions, particularly limited space, impervious subsoil and winter temperatures as low as -35° F., a septic tank and a covered intermittent slow sand filter, divided into 2 beds, were constructed in 1926 to dispose of the sewage from approximately 50 employees and their families in summer and 30 in winter, at the government utility area in Rocky Mountain National Park. The roof over the sand filter consists of wood with glass on the side exposed to the sun in winter. A general view of the sand filter is shown in Figure VI.

The effluent from the septic tank is applied to the sand filter by an automatic siphon. No difficulties have been

experienced in operating the filter in the winter with temperatures below zero for weeks at a time.

SETTLING TANKS AND OPEN TRENCHES

Settling tanks and open trenches in porous soil have been found a practical method of sewage disposal in several places, particularly where there is a comparatively small volume of sewage produced and trenches can be dug in porous soil in areas not frequented by visitors and where other methods of disposal are not practicable. The trenches are usually 2' in depth and 2' wide at the bottom, and at intervals of 100' there are dykes across the trench with pipes connecting the different sections. Disposal plants of this type are operated only during the summer season. A dense growth of algae develops in the sewage in the trenches and there are no odors noticeable 50' away. Each spring about $\frac{1}{2}$ " of surface material is removed from the trenches. This method of disposal is inexpensive, and where local conditions are favorable is a very satisfactory method of getting rid of sewage without danger of contaminating streams.

SETTLING TANKS, BROAD IRRIGATION, PONDS AND DISINFECTION

At the Mammoth Hot Springs area in Yellowstone Park there are housekeeping cabins, hotel, lodge, automobile tourist camp, general stores, with a

FIGURE VI—Glass Covered Sand Filter, Rocky Mountain National Park

permanent population consisting of employees of the government and public operators. This area is adjacent to the Gardiner River which is the emergency source of water supply for the town of Gardiner located on the river about 6 miles below the headquarters area. The population of the Mammoth Hot Springs area during the summer is approximately 1,250, and the permanent population during the winter averages about 125.

Two different methods of sewage disposal were considered for the Mammoth Hot Springs area. One included settling tanks, sprinkling filters, and disinfection of the final effluent which would be discharged into the Gardiner River, and the other included a settling tank and disinfection of the effluent which would be disposed of by broad irrigation, ponding, and disinfection of whatever sewage might overflow from the ponds. The latter method was adopted since it offered a greater measure of protection of the river against contamination, and the topography of the ground was favorable for this method of disposal. The component parts of the disposal system include settling tank, 3 chlorinators, broad irrigation, and ponds. One of the chlorinators is located at the headquarters area and is used to disinfect the small volume of raw sewage produced during the winter when the disposal plant is inaccessible on account of deep snow, and the other 2, one of which is used to disinfect the effluent from the settling tank and the other the overflow from the ponds, are operated during the summer and fall.

The effluent from the settling tank, during the time when the park is open to visitors and a large volume of sewage is produced, is discharged into open ditches which carry the sewage to the areas used for broad irrigation and to the ponds. During the winter the effluent from the settling tank does not

overflow the ditches and ponds, and broad irrigation is not necessary. A small amount of sewage which flows out of the ponds during the summer is discharged onto a sand bar and no doubt eventually reaches the river, but since it has been treated twice with chlorine and stored several days in ponds it is not believed the small amount of overflow from the ponds seriously contaminates the river water. An inspector visits the disposal system daily to adjust the flow of chlorine and regulate the flow of sewage to the areas under irrigation and to the ponds.

There is a slight odor of fresh sewage at the settling tank and a swampy odor near the ponds.

A few bacteriological analyses of samples collected during the summer from the overflow from the ponds before final disinfection showed that the *B. coli* group of organisms was present only occasionally in 1 c.c. portions.

This disposal plant was inexpensive to construct, costs only a small amount to supervise and maintain, and has produced very satisfactory results.

SUMMARY

The uniform policy followed with regard to the disposal of sewage in the national parks has been to avoid contaminating streams or interfering in any way with the use of streams for fishing or recreation, and to locate, construct, and operate treatment and disposal plants so that they will not only be free of odors and any other nuisance, but will conform to the high standards of the Park Service in relation to architecture and preservation of the natural scenery in the parks.

ACKNOWLEDGMENTS

The writer is indebted to P. A. Sanitary Engineer O. C. Hopkins and Sanitary Engineering Assistant H. R. Carlson for valuable assistance in the preparation of this paper, and to Hillard Hall and Russell White, opera-

tors, respectively, of the treatment plants at the Grand Canyon and Yosemite National Parks, for data furnished regarding the operation of these plants.

DISCUSSION

ARTHUR P. MILLER, F.A.P.H.A.

Sanitary Engineer, U. S. Public Health Service, New York, N. Y.

MR. Hommon's paper is of particular interest to me because, in 1921, I had the privilege of assisting him when he inaugurated the present system of controlling sanitary conditions in our national recreation areas. Three years of work in the western group of parks gave me a comprehensive picture of the magnitude of this task and of the peculiar difficulties which had to be overcome. In 1923, I was directed to return to the east and, about 1930, due to constantly increasing National Park Service activities in the eastern section of the country, Eastern and Western Divisions were established. Supervision of sanitation in the Eastern Division, which included all areas east of the Mississippi River and, in addition, Hot Springs National Park in Arkansas, was lodged in my office. I continued in charge of this work until 1934.

In 1921, in what is now the Eastern Division, the National Park Service administered only 2 areas, Acadia National Park in Maine, and Hot Springs National Park in Arkansas. I believe that very few people realize to what extent the number of national recreational, monumental, and historical areas under the careful supervision of that service has increased. Contrasted with the 2 areas in 1921, a summary this year shows the following:

TABLE I

National Parks	5	
National Historical Parks	1	
National Monuments	9	
National Military Parks	11	
Battlefield Sites	10	
Miscellaneous Memorials	4	
National Cemeteries	11	51
<hr/>		
National Parks (proposed)	3	
(Mammoth Cave, Shenandoah and Everglades)		
National Monuments (proposed) . .	2	5
<hr/>		
National Capitol Parks	1	
		<hr/> 57

These areas are not concentrated in any one section, but are well distributed throughout the East. Their geographical distribution is shown in Table II.

In the 2 older areas, Acadia and Hot Springs, sanitation has kept pace with the growth of the parks. Because of the importance of federal activities in the city of Hot Springs, the National Park Service is contributing generously to sewerage extensions and improvements and to new sewage disposal plants. The federal government's investment in those works has justified a controlling interest by the National Park Service in the selection of the designers and in the methods, efficiency, and continuity of plant operation. These interests are safeguarded in a

formal contract. I understand that a reputable mid-western firm has recently been awarded the work of designing this project.

There was recently completed in Hot Springs, a sewage disposal project for the public camp ground which included a system of collecting lines leading to a settling tank, the effluent from which is automatically pumped into sewage trenches on the only available tract of land, a fairly steep hillside adjacent to the main highway. The construction of these sewage trenches which are merely devices larger than the customary tile lines to permit infiltrating and seepage of clarified effluent into the ground, was complicated by heavy rock formations. Finally, blueprints had to be cast aside and sufficient patches of soil suitable for percolation sought on the ground. By this method we were able, eventually, to secure what we considered adequate seepage area. A similar system was designed for the principal public camp in Acadia. There, however, we were fortunate in having a small lake to receive the tank effluent.

One of the newer eastern areas, Colonial National Monument at Yorktown, Va., has received considerable attention. This monument has not yet developed to the point where a comprehensive sewerage project is warranted. Therefore, we solved the immediate problems by installing 4 separate settling tanks with arrangements for discharging clarified effluent into the ground. These installations were at different points in the federal territory, the idea being to provide sufficient facilities to care for the rapidly increasing tourist travel to this historical section. The need for definite and certain soil borings before the construction of any ground disposal scheme was demonstrated last year when we found one of our trenches ineffective. Tight soil, unobserved before design, has partially destroyed the usefulness of this particular installation and it will have to be expanded into a nearby area containing sandy loam of sufficient porosity to satisfy percolation requirements.

During the celebration of the Yorktown Sesquicentennial celebration in

1931, interesting problems were met in the provision of temporary sewage disposal facilities adequate to care for an estimated attendance of 100,000 people in 4 days. Utilizing large batteries of carefully attended and supervised pit privies, combined with a can system on a public water supply watershed, we successfully satisfied the needs of the situation without complaints.¹

At the George Washington Birthplace National Monument, small settling tanks with provisions for ground infiltration of the effluent have been built in four places. Here, again, the character of the monument did not justify a single system. Incidentally, before the organization of the Eastern Division, Mr. Hommon had much to do with the original installations in Colonial and George Washington's Birthplace National Monuments.

The other areas in this division are so new or have been acquired so recently that the provision of sewage disposal facilities has not yet progressed far. However, because of the procurement of funds from the Public Works Administration and on account of the need for usefully employing people without work, much activity is contemplated in many areas and some is going ahead at once.

In both the Great Smoky Mountain National Park (Tennessee and North Carolina) and the Shenandoah National Park Project (Virginia) headquarters development, public camping areas, privately owned but governmentally controlled concessions, will all require

systematically planned and substantial works for waste handling. These two large and beautiful areas situated in the midst of heavily populated sections will serve as recreation grounds for great numbers of people. These are not small areas. The final development authorized in the Great Smoky Mountain National Park includes 427,000 acres which makes it about two-thirds the size of Grand Canyon National Park, approximately four-sevenths as large as Yosemite National Park and somewhat larger than Sequoia National Park. A free and open park of this size in the center of the populous South is bound to attract many visitors.

Mammoth Cave National Park project (Kentucky) and the latest authorized one in the Florida Everglades; the National Historical Park at Morristown, N. J.; National Monuments like those at Fort Pulaski, Ga., and Fort Matanzas, Fla.; and National Military Parks such as Gettysburg, Shiloh, Vicksburg, Chattanooga and Chickamauga, are all being developed "for the benefit and enjoyment of the people." Keeping pace with the National Park Service, the Public Health Service will continue its coöperative efforts in the sanitary field insuring the guests of the national government the most adequate and convenient sanitary facilities possible under the circumstances existing at each site.

Significance of Bacteriological Methods in the Diagnosis and Control of Whooping Cough^{*}

PEARL KENDRICK, Sc.D., F.A.P.H.A., AND GRACE ELDERING†

*Associate Director, and Bacteriologist, Michigan Department of Health,
Bureau of Laboratories, Western Michigan Division,
Grand Rapids, Mich.*

A YEAR ago at the meeting of this society we¹ reported our first year's experience with routine cough plate examinations for *B. pertussis*. We presented particularly the methods employed, a summary of the year's findings, and a discussion of the practicability of the procedure under the conditions in our community. In the present report we wish to add the data of the second year and point out the ways in which our laboratory findings are being applied in the local health department in a program of whooping cough control, and finally, to outline the criteria employed in our choice of cultures and technic for the preparation of specific vaccines used in our whooping cough prevention study.

A few comments on the *etiology of pertussis* are pertinent. Some workers have been deterred from attacking the pertussis problem because of the doubt raised by some, notably pathologists, as to the etiologic significance of *B. pertussis* and the emphasis they place on

the possible rôle of an elusive filtrable virus in the disease. Intranuclear inclusions and interstitial bronchopneumonia have been noted in a certain per cent of pertussis autopsies. McCordock and Muckenfuss² regard this particular type of pneumonia as a type reaction to the presence of a virus and a bacterium. McCordock and Smith³ have analyzed the various possible interpretations of their findings of inclusion bodies and interstitial bronchopneumonia in whooping cough. By analogy with swine influenza they suggest that since similar inclusions are sometimes found in children with no history of whooping cough, pertussis may be a mild virus disease which is of little consequence without a simultaneous or secondary bacterial infection complicating the condition. In other words, the Bordet-Gengou bacillus represents the bacterial component in a hypothetical virus-bacteria complex necessary for the production of the whole picture of whooping cough. Even were this proved, the diagnosis of the disease and probably specific methods for prevention would depend upon the bacterial component. The fact remains, however, that such a virus has not been demonstrated while the association of *B. pertussis* with the disease is unquestionable.

^{*} Read before the Laboratory Section of the American Public Health Association at the Sixty-third Annual Meeting in Pasadena, Calif., September 4, 1934.

† With the coöperation of the City Health Department of Grand Rapids, A. H. Edwards, M.D., Health Officer.

The finding of this organism in cases of whooping cough—from the mildest to the most severe infections—approaches 100 per cent as the technic approaches perfection, and the organism is not found in the absence of this disease. Further, pertussis has been produced by the culture in laboratory animals as evidenced by more recent reports such as those of Sauer and Hambrecht,⁴ Rich, Long, Brown, Bliss and Holt,⁵ and Shibley,⁶ who used special technic to assure the freedom of the culture from a filtrable virus; and experimental pertussis in children has been reported by MacDonald and MacDonald.⁷ Added to this are the encouraging reports of some, notably Madsen and coworkers⁸ and Sauer⁹ on the results of specific vaccines prepared from recently isolated cultures. A summary of various data in favor of the etiologic rôle of *B. pertussis* by Miller¹⁰ gives considerable material relevant to this subject.

On the basis of the accumulated evidence we believe there is no excuse for us to cease our efforts toward whooping cough prevention. Rather, there is good reason for proceeding on the assumption that *B. pertussis* is the cause of whooping cough; and accepting this, the study naturally centers around the organism *B. pertussis*.

THE BACTERIOLOGICAL DIAGNOSIS OF WHOOPING COUGH

Methods—The technic employed in cough plate diagnostic procedure has been outlined in previous communications.^{1, 11} The exposure of cough plates has been done almost entirely during the past year by 25 nurses in the Bureau of Public Health Nursing.* This is part of a coöperative plan instituted about a year ago between the Health Department of Grand Rapids and the physicians of the city. Upon the re-

quest of a physician the nurse in the particular district secures a diagnostic cough plate, and the laboratory findings are reported to both physician and City Health Department. If the first plate is negative or unsatisfactory and the diagnosis of whooping cough has not been ruled out in the meantime, a second plate is obtained. If either plate is positive or if both are negative and the patient has definite clinical signs of whooping cough, isolation is established and release plates are taken as explained later under the section on release measures.

Between November 1, 1932, when diagnostic cough plate service was instituted on a routine basis and August 1, 1934, 984 plates were examined, not including 40 which have been reported as unsatisfactory for some reason such as insufficient inoculation or overgrowth with contaminants. The results are summarized in Table I.

TABLE I
SUMMARY OF COUGH PLATE EXAMINATIONS

CLINICAL DIAGNOSIS	Number of Cough Plates		
	Posi- tive	Neg- ative	Total
Whooping cough through 4 weeks	254	160	414
Post-whooping cough 5 wks. to 6 mos. after onset	13	242	255
Other than whoop- ing cough	0	218	218
Clinical data not available	0	97	97
Totals	267	717	984
Unsatisfactory			40

In clinical whooping cough, the correlation of the stage of disease with positive cough plate findings is always of interest and significance. Particularly, such findings give us an indica-

* Under the direction of B. Randle

tion of the probable period of infectivity and therefore of a reasonable isolation period. In Table II are the results of plates from 332 cases of whooping cough.

TABLE II

WHOOPIING COUGH CASES:
SUMMARY OF PLATES CORRELATED WITH
STAGE OF DISEASE

WEEK OF DISEASE	Posi- tive	Neg- ative	Total	% Pos- itive
1	91	25	116	78
2	80	45	125	64
3	58	36	94	62
4	25	54	79	32
5	10	56	66	15
6	1	30	31	3
Totals	265	246	511	

By comparison with our report of a year ago,¹ it will be seen that with the addition of more material, the percentages of positive plates during different weeks of disease have been changed somewhat but the essential picture is the same. The data suggest that a relatively high per cent of patients are infective throughout the first 3 weeks of disease, a progressively smaller per cent continue so through the 4th and 5th weeks, while only an occasional individual remains so after the 5th week.

Comment—The increasing number of physicians taking advantage of the cough plate diagnostic service is an indicator of the assistance bacteriological findings give them. While 22 used the cough plate service during the first year, 70 have received laboratory reports during the second. Many instances attest to the aid these reports have given in establishing the diagnosis of the atypical, light, or second attack of whooping cough, and in obtaining an

early diagnosis before the characteristic cough has developed. The experience of these 2 years leaves little room for doubt as to the practicability and value of the bacteriological diagnosis of whooping cough.

BACTERIOLOGICAL FINDINGS AS A BASIS FOR ISOLATION AND RELEASE

PROCEDURES

The data on the presence of *B. pertussis* at various stages of the disease (see Table II) suggest that if an arbitrary isolation period were to be chosen at the termination of which over 90 per cent of the patients would be noninfective, it would be 5 weeks. A week earlier than this, an appreciable number would still be infective.

The feasibility of using release cultures in whooping cough has been recognized by certain authors, for example Lawson and Mueller,¹² but we have seen no report of their actual application. For the past year we have been attempting such a test. The relatively low incidence of whooping cough in the city during this time has made possible the extra labor involved in the various divisions of health department and laboratory, though it has limited the quantity of our data. As an indication that the regulations as tested are not considered impossible from the standpoint of administration, they were recently incorporated in the local communicable disease regulations, as follows:

1. Cases and suspected cases shall be reported.
2. Patients shall be isolated on the basis of either clinical or bacteriological diagnosis.
3. A warning placard shall be placed on the home.
4. Patients shall be released 35 days after onset of disease (first symptoms), if the cough plate is not employed.
5. A patient may be released on the 28th day after onset of disease if there have been two consecutive negative cough plates taken at least 24 hours apart, the first one taken not earlier than the 21st day after onset.

If one of the first two release plates is positive, the third plate should not be taken before the 28th day.

6. Every effort shall be made to encourage voluntary isolation of a patient while the first cough plates are being examined or until the clinical diagnosis has been made.

Results of the application of bacteriological release—The findings of actual release plates agree very closely with what might be expected from the accumulated data on the per cent of positives during the various stages of the disease. The results to date are summarized in Table III.

TABLE III
RELEASE COUGH PLATE FINDINGS

Release cough plates		Patients for release		
Week obtained	Number of plates	Total patients	Released	% Released
4th	86	58	33	57
4th and 5th	125	69	63	91
4th, 5th & 6th	155	83	82	99

In starting our study of release procedures, we were not always able to obtain a complete series of plates from each patient, so the 3 periods analyzed—the 4th week; 4th and 5th; and 4th, 5th, and 6th weeks; respectively—are considered as separate units. For instance, if a patient had 1 or more positive plates during the 4th week and hence was not ready for release, but for some reason further plates were not secured, data pertaining to him were included only in the first period.

Our findings show that 33 of 58 patients or nearly 60 per cent were released on the basis of negative cultures taken during the 4th week. Further plates, all negative, were submitted by some of the 33 patients after the 4th week,

thus strengthening the basis for their early release. Of the second group—those included during the 4th and 5th weeks—only 6 of 69 individuals, or less than 10 per cent, remained positive at the end of the period. In the cumulative data of the 4th, 5th, and 6th week interval, only 1 of 83 cases had not been released at the end of the 6th week. In general, the application of the cough plate method shortens the isolation period for the majority of cases and lengthens it for a relatively small group.

It is of interest to follow the findings of a series of plates from a few individual cases for release. In Table IV are shown 5 such series. George and Jerry, who are typical of over half the cases, had 2 consecutive negative plates during the 4th week. Allowing 4 days for incubation of the plates before the laboratory report is made, such patients would be released about 28 days after onset. Donald's and Richard's first release plates were positive and it was the end of the 5th week before they could be released. Marvin's case proves the desirability of more than 1 release plate, since his first was negative followed by 2 positives. A requirement of more than 2 negative plates would no doubt add an occasional positive finding

TABLE IV
A FEW TYPICAL FINDINGS IN CASES FOR RELEASE

Patient	Cough plates: results and day of disease		Day of release by laboratory report
	Diagnostic	Release	
George	+ 4	-23-24	28
Jerry	+ 9	-25-26	30
Donald	+ 7	+24-29-30	34
Richard	+ 9	+23+24-30-31	35
Marvin	+14	-27+29+34-35-40	44

but we believe the additional burden not warranted. Further, continued isolation through the 4 day interval between receipt of the plate at the laboratory and the negative report adds a margin of safety.

With the regulations as tested, our findings suggest that in whooping cough, bacteriological release can be made as efficient as in certain other diseases where it is accepted without question. Whether the procedure can or should be applied generally is a question for study under the conditions of different communities.

B. PERTUSSIS VACCINE PREPARATION

If *B. pertussis* is the etiologic agent in pertussis, there is a sound basis for expecting some protection against whooping cough from a suitably prepared, properly administered vaccine. In general, the literature since 1906, when trials of vaccine were begun, does not give convincing support for such protection. An analysis of the different reports, however, shows little basis for comparability of results. Some workers have used vaccine after the onset of disease, some after exposure but before symptoms, a few at a considerable time before exposure, and some at undefined times. The age groups, geography and epidemiology have all supplied variable factors; the dosage has not been sufficiently considered; and adequate controls frequently have been lacking. In the light of more recent knowledge of the antigenicity of cultures and with the encouragement of the more recent results of Madsen and coworkers⁸ and of Sauer,⁹ there is good reason for a reinvestigation of the value of *B. pertussis* vaccine. The problem is one for a carefully controlled, longtime study, and conclusive evidence must await an analysis of the results obtained by different investigators.

In the meantime, much is to be gained in a definition of conditions under which

different investigators are working. It encourages open discussion of the different factors involved which may lead to some general agreement on the essential requirements for technical procedures. It is in this spirit that we briefly outline the methods employed in the preparation of *B. pertussis* vaccine as used in our study—not as the perfect solution of the complex problem. The methods represent to us a starting point for future studies—a line of procedure to be adhered to in its essentials for a sufficient time to give our results meaning and to furnish a sound basis of judgment.

Selection of suitable cultures—The first point is the suitability of the cultures to be used. Lack of conformity among different workers on this point could provide ample explanation for widely divergent results.

If certain profusely growing old laboratory strains of *B. pertussis* were satisfactory, vaccine preparation would be relatively simple. We have reason to question their suitability since we know that they may be serologically quite distinct from cultures just isolated from patients with whooping cough—cultures which, in general, form a homogeneous serological group, "Phase I" of Leslie and Gardner. Madsen⁸ and Sauer⁹ have recognized this in their specification of "recently isolated" cultures. The date of isolation has been a helpful temporary criterion but it is an inexact and superficial one. Just where shall we draw the line between a "recently isolated" and an "old" culture? Can we be sure in substituting a week-old culture for one 6 months old that we have improved the antigenicity of our vaccine? We agree with Hawley and Simmons¹⁵ in connection with typhoid vaccine, that their practical problem may be more concerned with determining and maintaining the desirable state of their culture than with the search for one recently isolated.

In *B. pertussis* vaccines the essential problem is to determine the antigenically effective state and the means of sustaining it. Above all, we need *adequate criteria* for judging the state of the culture. While the final test is whether the vaccine protects against whooping cough, we must have practical laboratory indicators for accepting or refusing any particular culture for a lot of vaccine. Accepting the thesis that the culture just isolated from a patient with whooping cough is the most likely to be antigenically active in a vaccine, we have studied numbers of such cultures in an effort to arrive at the significant characteristics by which to judge them. In these studies,¹⁰ we have made use particularly of serological relationships, pathogenicity for mice and guinea pigs and the intradermal test in the rabbit. We believe they have demonstrated that certain characteristics are of such uniformity and significance as to furnish reliable guidance in judging the antigenicity of cultures. In the present state of our knowledge we accept the following *criteria for selecting cultures* for a vaccine:

1. *Typical morphology and growth characteristics* including hemolysis on Bordet-Gengou medium. These are described by various authors, including ourselves.¹

2. *Agglutination to high titer* by smooth strain anti-serum (Phase I, Leslie and Gardner). For agglutination tests we use the rapid method previously described.¹¹

3. *Phase I agglutinin production* in the rabbit. The rabbit is injected intravenously at 3 day intervals with 0.2, 0.4 and 0.8 c.c. per kg. weight, successively, of a 10 billion per c.c. saline suspension of organisms killed with a preservative such as merthiolate 1:10,000, or phenol 0.5 per cent. A bleeding on the 6th or 7th day after the 3rd dose is usually from 1:2,000 to 1:5,000 final titer, rapid test (1:10,000 to 1:25,000, equivalent titer) with any Phase I culture.

4. *Typical rabbit skin reaction* of hemorrhagic necrosis. A dose of 0.1 c.c. of a 1 billion per c.c. living, saline suspension of a Phase I culture gives a characteristic reaction. Typically, within a few hours there is an ischemic, indurated area at the site of inocu-

lation. By 24 hours there is a purplish hemorrhagic center which progresses to necrosis, scab formation and final scarring. This reaction has been recognized by several workers and recently described by Gundel and Schlüter.²⁰ Its value in studying *B. pertussis* cultures was discussed in a previous paper.¹⁰

While developing these criteria, we have also given attention to the date of isolation. In general, we have used 6 cultures for each lot—all isolated within 3 months and 3 of them within 1 month. We believe this age factor is unimportant, provided the cultures have the characteristics described. Further, we are not convinced that several cultures are superior to one, properly chosen, but we continue to employ several while this point is under study.

Choice of technical methods—Having decided upon the cultures, we are confronted with the necessity of choosing technical procedures. Our objective should be to grow the cultures in such a way as to maintain their *antigenicity*; to determine the conditions of *maximum growth* consistent with maintenance of the antigenic state; to kill and preserve them *without denaturing* the active antigens; and, finally to provide a *safe* product. In choosing particular technic, we have been guided by practicability in so far as it did not conflict with these essential requirements.

We have found that cultures maintain their Phase I characteristics on the Bordet-Gengou medium used for cough plate,¹ so have used this medium in growing cultures for vaccines. We are trying out a similar medium with added veal infusion and peptone, in line with that used in Copenhagen and described by Miller.¹⁴ This supports a heavier growth, and our adoption of it awaits only further tests of the antigenicity of the cultures.

The *kind of blood* to use in the medium has been emphasized by Sauer¹⁷ in his insistence upon human blood. As to the maintenance of Phase I antigenic properties, we have found

no difference between human and sheep's blood. As to the safety factor, there are no convincing theoretical grounds, and in our experience with the inoculation of several hundred children, there is no experimental basis for any fear in this regard. Since we have found human and sheep's blood equally satisfactory, we use sheep's blood as it provides a far more uniform, constant, and less limited supply than is available from human sources. In the meantime, this point is under continued study.

We need to know the *optimum state* with respect to antigenicity in which to administer the vaccine. Most vaccines have been suspensions of whole organisms. Kreuger, Nichols and Frawley¹⁸ recently described a water-clear pertussis antigen prepared by grinding washed cultures in a ball mill for 12 hours and subsequent filtration through a collodion membrane. We shall watch the use of this with great interest. As for our own studies, our first aim is to satisfy ourselves in a carefully controlled series of injections, as to the results of the *whole culture vaccine*. If definite protective value can be established for such vaccines by different investigators, and the conditions of their success defined, there will be a sound basis for the judgment of modified and improved antigens.

The question of *washing the suspension* arises. We have to choose between an unwashed product which carries with it agar, blood and other medium derivatives and a washed vaccine relatively free from them. A washed product surely is preferable if significant antigenic properties are not lost. Since we have found the washed live culture capable of giving a typical skin reaction and a vaccine, even after 3 washings, capable of stimulating Phase I agglutinins rapidly and in high titers, we decided on a *washed product*. The growth is washed off the medium

into physiological salt solution, its turbidity adjusted roughly to approximately 10 billion organisms per c.c. by comparison with known suspensions, and the organisms washed once by centrifugation and the supernatant fluid discarded. The sediment is resuspended in saline and filtered through cotton.¹¹

As to the killing and preserving of the vaccine in such a manner as to leave the active antigens unimpaired, there is need for further study—in this as in other vaccines. We have avoided the use of heat and have killed the cultures by chemicals. We have used merthiolate 1:10,000 and in some lots phenol 0.5 per cent. In either case we obtain a vaccine which is effective in stimulating Phase I agglutinin production in the rabbit.

The method of *standardization of the density of suspension* is another point for consideration. Our first counts by Wright's method showed a great variation. We made an extended series of counts by this method and in different types of chambers in comparison with the determination of per cent of suspension by the Hopkins tube, and concluded that the Hopkins method gives far more uniform results and that it is an immeasurably more simple method of standardization. Our comparative tests indicate that a 0.3 per cent suspension by this method represents approximately 10 billion organisms per c.c. The suspension to be tested is adjusted roughly by turbidity to slightly heavier than that required, a volume of 5 c.c. is centrifugated at 2,500 r.p.m. in a Hopkins tube for 30 minutes, estimations made from the measured sediment and the suspension adjusted to 0.3 per cent.

In brief, our vaccine is a once-washed, 0.3 per cent suspension of Phase I *B. pertussis* grown on Bordet-Gengou medium enriched with 15–20 per cent sheep's blood. The organisms are killed

with a preservative such as merthiolate 1:10,000 or phenol 0.5 per cent allowed to act at cold room temperature for a week or more. The product is tested for purity and sterility by the usual procedures of staining, aerobic and anaerobic broth cultures and Bordet-Gengou medium cultures; for safety by guinea pig tests; and for antigenicity as indicated by agglutinability with Phase I serum and by ability to produce Phase I agglutinins in the rabbit rapidly and in high titer.

COMMENT

As public health workers, we need to realize the seriousness of whooping cough as a communicable disease of childhood. The important place it holds as to cause of mortality, morbidity and pathological sequelae is emphasized in a recent report of the League of Nations Health Committee.²¹ It is pointed out in this report that the death rates from whooping cough and measles have declined more slowly during the past 30 years than have those from diphtheria and scarlet fever, and consequently their relative importance as a cause of death has increased. During 1926-1930, in 6 countries including the United States, whooping cough was responsible for about one-third of the total deaths from diphtheria, scarlet fever, whooping cough, and measles. In the period 1927-1929, the same proportion held true in the United States for the total deaths, while in the age group 0-4 years, whooping cough was responsible for 43.5 per cent of all deaths from these 4 diseases; diphtheria, 30.6 per cent; measles, 19.1 per cent; and scarlet fever, 6.6 per cent.

The need for a study of whooping cough control measures is obvious. While the problem is a complex one, we should not avoid it as being impossible of solution. A note of hope is

struck in an editorial of the *British Medical Journal*¹⁹:

A survey of all this recent work leaves us with hope that this plague of the nursery and school, which in 1932 caused 300,000 infections in the United States and upwards of 6,000 deaths, will in time be as controllable as diphtheria now is to those who choose to benefit by methods at our command.

We believe that bacteriological methods as discussed in this paper offer reasonable promise of aid and deserve a thorough trial under conditions as favorable to their success as we can make them. The more widespread their use, the more centers there will be for studying various phases of the whole problem—for it is only in such centers that there is the necessary background for a comprehensive study of the subject.

SUMMARY

We have summarized the results of nearly 2 years' routine laboratory examinations for *B. pertussis* and have pointed out their application to the diagnosis of early, light and atypical whooping cough; to isolation and release procedures; and to the study of specific methods for whooping cough prevention.

Whooping cough isolation and release procedures which have crystallized out of our bacteriological study are now under test as a part of Grand Rapids Health Department communicable disease regulations.

Criteria for the selection of cultures and for the choice of technic employed in preparing vaccines for whooping cough prevention studies have been discussed.

Weight of Children

1. Averages of weight of children in 1934 show no consistent or striking differences from averages of weight for the period 1921 through 1927.

2. The variability of body weight (measured by the standard deviation) is not, for boys, consistently different in 1933 and 1934 from that observed in the 1921-1927 period. For girls, weight is more variable in both 1933 and 1934 than in the earlier period.

3. The proportion of boys 12 per cent or more below average weight has not increased in 1933 or 1934, while the proportion of girls so designated is slightly greater, both in 1933 and in 1934, than that observed for the years 1921-1927.

4. Average annual gains in weight are lower for the year 1933-1934 than those calculated for the 1921-1927 period. The average for the several age-sex groups, of the ratio

Average annual gains in weight, 1933-1934

Average annual gains in weight, 1921-1927

equals 91.5 per cent. Comparing this ratio with similar average ratios for the separate

years 1921-1927 shows, however, that the relative gain for 1933-1934 is not significantly lower than that recorded in 1924-1925, a year in which general economic conditions were presumably much better than in 1933-1934. This finding, together with the fact that the actual weight of children has not decreased in the past decade, is taken as evidence that the recent economic depression has not materially affected the growth in weight of a representative sample of school children.

5. A supplementary study of the weights and weight increments of children from families in different levels of economic status in 1933 and 1934 shows that approximately the same differences are to be found as have been observed in times previous to the depression. From this it is concluded that there has been no obliteration or widening of class differences during the depression.—

Carroll E. Palmer, M.D., Further Studies on Growth and the Economic Depression, *Pub. Health Rep.*, Dec. 7, 1934, pp. 1468-1469.

Some Factors in the Epidemiology of Malaria*

HENRY HANSON, M.D., F.A.P.H.A., MARK F. BOYD, M.D.,
F.A.P.H.A., AND T. H. D. GRIFFITTS, M.D.

*State Health Officer; Director Malaria Research Division; and Director
Malaria Control Studies, Florida State Board of Health,
Jacksonville, Fla.*

THE factors concerned in the epidemiology of malaria are so numerous that it is difficult to choose the one appropriate to the opening of a discussion of this nature.

Owing to limited time the usual historical references must be left out and those interested in malaria history are referred to a voluminous literature on the subject. The geographical distribution of malaria covers a belt around the world wider than the tropics, extending irregularly into the temperate zones on both sides of the equator. In the north it is found to extend to points varying from 45° N. L. to 60° N. L. in the old world, and in the new world as far north as 40° to 42° N. L. To the south it covers nearly all South America with severe manifestations in the northern portion, along the Magdalena, Orinoco, and Amazon Rivers, and in the Guianas.

It is not practical to discuss the epidemiology of malaria on a world-wide basis, because such an effort would require volumes and more time than is allotted to the entire program of the Association.

Factors influencing epidemiology are:

1. Presence of persons with parasites in the blood

2. Presence of Anopheles of a species effective as a carrier

3. Accessibility of human parasite carrier to Anopheles

4. The presence of gametocytes in the blood of the parasite carrier

5. The age of the sporozoites, i.e., the length of time the mosquito has carried the infective agent. Boyd has found that infectivity is reduced with the age of the infected mosquito

6. Immunity to prevailing strains:

A. Latent infection. In the malaria research division of the State Board of Health, Boyd and Stratman-Thomas found it difficult to re-infect with the same strain individuals who had recovered spontaneously from an attack produced by that strain. The protective mechanism is thought to be associated with a continuing residuum of the infecting strain, which is spoken of as latent infection.

B. Racial tolerance to certain species of the parasite. For example, the negro is apparently highly resistant to *Plasmodium vivax* (benign tertian) but susceptible to *P. falciparum*. Boyd has found it very difficult to infect negroes with *P. vivax*, in fact, in some cases adult negro males "have been found with a tolerance that successfully resists the application of 16 *Anophelines* of proven infectivity." The refractoriness is believed to be racial and not acquired. (33rd Report Florida State Board of Health, page 76.)

7. The prevailing external temperature controls the length of time required for the development of the parasite in the mosquito, e.g., at 20° C. (68° F.) 17 days is required to complete the sporogenous cycle in the mosquito (extrinsic incubation). Tempera-

* Read before the Epidemiology Section of the American Public Health Association at the Sixty-third Annual Meeting in Pasadena, Calif., September 3, 1934.

ture and humidity also play an important part in the longevity of the mosquito, and, seasonally, the period of mosquito activity, hence the importance of relatively high winter temperatures in Florida.

The intrinsic incubation of tertian malaria varies from 10 to 20 days—longer periods are exceptions. Eighty-five and 97 days are said to have been observed. The parasite (*P. vivax*) is often found some days before the manifestation of clinical symptoms, sometimes 6 days before onset, a fact which may or may not influence the epidemiology (Boyd).

Gametocyte production is more constant and abundant in primary attacks of tertian than in recurrences. Consequently, mosquitoes feeding on a patient in the primary attack may develop more cysts and sporozoites than those feeding on patients in secondary attacks with a lower gametocyte production.

In *P. falciparum* (E.A.) the extrinsic incubation is 23 days at 20° C. according to Florida findings; the intrinsic is 8–15 days. Both the white and Negro

racess show a high degree of susceptibility to quartan.* Extrinsic incubation is 35 days. Intrinsic incubation is 27 to 42 days. Quartan malaria is more severe than tertian and more exhausting, but comparatively rare in the state.

In this paper we are dealing with factors in the epidemiology of malaria chiefly as we see it in Florida. Conditions which prevail in Northern Florida are very much like, if not identical with, those in Southern Georgia and Alabama.

1. The geographic distribution as represented by deaths reported to the Bureau of Vital Statistics of Florida has been the basis on which incidence is computed and is shown in Tables I and II for the years 1932 and 1933. In comparing the two tables it is noted that there was a decided increase in the number of deaths reported in 1933 as compared with 1932 (373 vs. 233).

The greatest concentration of cases occurs in the northern counties, the central group, opposite the southwestern portion of Georgia and southeastern

* In experimental work or malaria therapy.

Alabama and south through the central portion of the state as far as Polk County beyond which the incidence becomes much less significant.

In a country within the latitude of high malaria incidence there is a tendency to call all ill-defined fevers malaria, rendering difficult an accurate determination of morbidity, which can only be ascertained by spleen and blood smear surveys. In order to judge how nearly

our vital statistics represented the epidemicity or endemicity of malaria in the state, a spleen index of school children was taken in 1931 by Boyd and Stratman-Thomas in the 14 counties lying between the Apalachicola and Suwannee Rivers (*Thirty-third Annual Report—A Decade in Public Health*, Florida State Board of Health). Of those examined, the spleen index was 15.2 per cent among 2,502 Negroes,

and 34.2 per cent for 3,009 whites, or an average for both races of 25.6 per cent.

The area involved geologically is underlaid by limestone, and has numerous depressions forming sinks, lakes, and ponds of various sizes, the edges of which, and frequently much of the surface, are favorable to *Anopheles* breeding.

Further reference to the tables shows a greater mortality in certain counties such as Jefferson, Madison, Suwannee, Jackson, Leon, etc. The incidence is mainly rural. The urban rate is very low, although the disease is frequently contracted by persons who have been away from the cities at night.

2. Annual fluctuations are shown in Figure I, in which there is an apparent peak every 10 years with secondary intermediate peaks. Meteorological records show corresponding peaks in the spring and summer rainfall. The precipitation in the years 1924-1925 and early in 1926 was largely winter rain (see Boyd charts).

Aside from the rainfall and mosquito production it has been suggested that the fluctuation in incidence bears a relation to immunity acquired by a considerable portion of the population during the peak years.

Boyd has shown that persons who show clinical recovery from the acute attack without specific treatment were not susceptible to reinfection by the same strain of the parasite, and there is some indication of tolerance to a heterologous strain. How long this tolerance lasts is not known.

3. *Anopheles* of the state are: *A. quadrimaculatus*, *A. crucians*—two varieties (fresh and salt water), *A. punctipennis*, *A. atropos*, *A. walkeri*, *A. barberi*.

While the 6 foregoing species are all potential vectors, *quadrimaculatus* is by far the most important. This species is found over the state extending as far

south as Collier and Broward Counties and the northern third of Dade County, with greatly lessened production along the coasts. *Anophelines* of any species have not been found in numbers sufficient to be of sanitary importance, south of the east and west portion of the Tamiami Trail.

The distribution of species has an important bearing on epidemiology. The malaria incidence in our state coincides with the *A. quadrimaculatus* production, which is most accurately determined by the search for and the finding of adults. Observations on breeding made by dipping for larvae will not furnish the necessary knowledge concerning emergence of imagoes.

In so far as the Florida problem is concerned, the findings of Boyd in his work on the rearing of *Anopheles* (*quadrimaculatus*, *crucians*, etc.) in which he has found *quadrimaculatus* easily infectable with *P. vivax*, and *P. falciparum* together with the fact that *quadrimaculatus* is a known pond and lake breeder, lead us to believe that *quadrimaculatus* emergence is the main factor.

4. So far as the relative importance of the different species is concerned, *quadrimaculatus* is responsible for most of the malaria in the state. Other species, such as *crucians*, *punctipennis*, and *atropos*, are proven carriers but are regarded as epidemiologically unimportant. A factor of great importance is the habit, or tendency of *quadrimaculatus* to invade dwellings and sleeping quarters. Areas with heavy *crucians* production show relatively low case incidence of malaria, as determined by blood indices taken by Grifftts. For example, Bradford County at the time of the survey showed fairly heavy *crucians* production and infestation, but only 1.9 per cent of 1,643 school children were blood positive. Of those positive 37.5 per cent were E.A. (*P. falciparum*), 18.8 per cent benign

tertian, and 3.1 per cent were mixed infection. Of 6,161 school children examined during 1933, outside of the main endemic area, 5.4 per cent showed parasites on microscopic examination, a finding which seems to harmonize with the mortality statistics for the same area.

Leon County lying within the main endemic area, and having relatively high reported mortality, showed a blood smear index of 9.5 per cent among 655 children of which 87.1 per cent were *P. falciparum* (E.A.) and 4.9 per cent *P. vivax* (B.T.) and 1.6 per cent mixed, with 4.6 per cent species undetermined. Of the 9 schools examined the rate varied from 6.6 per cent to 41.7 per cent.

In Levy County 39 schools were examined, in 7 of which no positives were found, the remaining 32 varying between 2.7 per cent and 84.2 per cent. In the school showing 84.2 per cent positive, 81.2 per cent were E.A. infectious and 12.5 per cent B.T., while in 6.3 per cent the species were not determined.

During the past 2 years (1932-1934) 15,257 school children (mostly rural) have been examined (thick blood films) for malaria infection. This survey included the primary grades of 294 white and Negro schools in 16 counties in the northern section of the state. The rate of infection was found to be 6.1 per cent with 70.1 per cent *P. falciparum*, 21.7 per cent *P. vivax*, 0.2 per cent *P. malaria*, 1.7 per cent mixed *P. falciparum* and *P. vivax*, and 6.3 undetermined. As expected, the area of reported high mortality corresponds with a relatively high *P. falciparum* rate.

Fluctuations in precipitation, periods of drought followed by heavy rain, are followed by a somewhat corresponding fall and rise in the malaria morbidity and mortality curves (see Figure I).

The foregoing discussion has dealt briefly with a few of the biological and climatological principles which influence the appearance and continuation of malaria in a section of the southeastern United States, without reference to the influence of sanitary engineering or medical control measures.

Measles Epidemic Broke Record

MEASLES has broken a 21 year record. The number of cases reported each week has been higher than at any time since the U. S. Public Health Service began keeping records of this disease in 1912.

The epidemic has just begun to abate,

less than 30,000 cases being reported weekly now. At the peak of the epidemic, during the first week in April, 35,000 were reported by state health officials to the U. S. Public Health Service in Washington, D.C.—*Colorado Medicine* 31, 11:379 (Nov.), 1934.

A Study of Diphtheria Immunization in Preschool Children in Assumption Parish, La., 5 Year Period 1929-1933

P. M. PAYNE, M.D., F.A.P.H.A. (*Life Member*)

Director, Assumption Parish Health Unit, Napoleonville, La.

THE population of Assumption Parish is 15,990, and, according to the White House Conference reports, the preschool population of an average American city is 13 per cent of the population as a whole. Of course it is considered that the rural population is somewhat more prolific than the urban, therefore there should be a slightly larger percentage of preschool children in a rural community than in the city. On the other hand, I believe the infant mortality is somewhat greater in rural than urban populations, so there is after all not a great difference in the preschool population of the city and the country as a whole.

In looking over our birth records for the above period we find there have been 2,101 births in the 5 years, 1929-1933 inclusive, or an average of 420 births per year. Now, it will be seen that 13 per cent of 15,990 is 2,078 or very close to the average for city people, a little the rise of it in fact, 2,101, or 13.13 per cent.

<i>Population</i>	<i>Estimated Preschool Population</i>
15,990	13.13% of 15,990 equals 2,101

This tabulation shows that we are getting a very accurate birth reporting as the figures tally very closely with the statistical data on which the White House Conference report was founded.

A study of the diphtheria case inci-

dence shows the number of deaths occurring from that disease and the number of diphtheria immunizations completed in the parish since 1929.

Cases of Diphtheria, 1929-1933 inclusive

1929—4 cases, ages: 10 years (1), 6 yrs. (1), 3 yrs. (1), 1½ yr. (1).

Deaths, none.

1930—5 cases, ages: 9 years (1), 6 yrs. (1), 5 yrs. (2), 8 months (1).

Deaths, none.

1931—7 cases, ages: 8 years (2), 7 yrs. (1), 4 yrs. (2), 2 yrs. (2).

Deaths, 1, age under two years.

1932—5 cases, ages: 7 years (1), 6 yrs. (1), 4 yrs. (2), 26 yrs. adult (1).

Deaths, 1, age six years.

1933—2 cases, ages: 3 years (1), 2 yrs. (1).

Deaths, none.

We will pass over the immunization of some 4,000 or more school children in the parish before we were able to induce parents to permit us to immunize the younger children, from 6 months to 6 years, in which latter group diphtheria is most prevalent and most fatal.

In the entire period, 1929, 1930, 1931 we immunized but 117 children under 6 years of age, but as there occurred 7 cases of diphtheria in 1931, 5 of them under 5 years of age, with 1 death, a child of 1 year and 3 months, we determined to make a house to house canvass for preschool children, and the result was such as to stimulate us to

further effort in 1932. In 1932 we gave 601 children under 6 years of age two doses of toxoid and as there were no reactions of consequence it helped to induce parents to have their preschool children immunized, and the year 1933 showed a net 1,036 children under 6 years having had either the one dose, alum precipitated or the two dose toxoid.

From the foregoing it will be seen that up to the end of 1933 we had a total of 1,754 children under 6 years of age immunized against diphtheria, and the summer vacation (1934) will be devoted largely to a further round up of these children under 6 years, to the end that by January 1, 1935, we hope to have no less than 95 per cent, or more of the preschool children immunized. Every physician in the parish will be asked to coöperate in this work, and when one studies the matter closely it will be seen that after all, if the physicians immunized every child born in the parish, year by year, and that if they received \$1 per immunization for their fee, it would, after dividing the entire amount equally among the 9 physicians, give each but approximately \$40 per year, or if only half of them, which is more likely, were immunized it would be but about \$20 per year.

Diphtheria can, should, and must be prevented. I hold that each and every family physician should urge upon each parent at the time of the birth of a baby that the child should be immunized against both diphtheria and smallpox by the time the child is 1 year old, and that if the physician prefers to do it himself rather than delegate the matter to the health department that in a large majority of the cases the family will do as he says and pay the small fee required. Certainly, the immunization should be done, especially when we know that in these little ones is where the greatest danger lies.

With the narration of an interesting incident which occurred in one of the

cases of 1932, a death in a child 6 years old, we will bring this study to a close. It is as follows:

A child 6 years old was brought to one of the typhoid clinics and was given typhoid vaccine along with the parents. At a subsequent visit to the typhoid clinic another child, a baby about 1½ years old was brought but instead of giving this baby the typhoid vaccine we advised that they let us give it the diphtheria toxoid (two doses) which was done. The 6 year old was not given toxoid at the time on account of the typhoid vaccine.

A few months slipped away and the little 6 year old who had not been given the toxoid was taken sick and the family doctor suspected diphtheria and so advised us, asking if she had had toxoid, the mother stating that she had been given some "shots." On looking up her record it was found that she had not been given the toxoid, and a smear that had been sent to the Laboratory was reported "positive for diphtheria." She was given antitoxin, 20,000 units, but died within 24 hours from that time.

Meanwhile, the baby that had been given two doses of toxoid a few months before had been sleeping with the child who now had developed diphtheria, but no sign of the disease appeared in the little one, smears from its throat being negative, and while it had had every opportunity to develop the disease it was not in the slightest degree affected.

Of course, one case is not enough on which to base a conclusion that the child was protected by its two doses of toxoid, yet it is well worth relating and we are sorry indeed that we did not give the little 6 year old toxoid instead of the typhoid immunization.

Later. As of November 1, 1934, a total of 614 preschool children have been added to the above, all of them receiving one dose, alum precipitated toxoid, making 833 preschool children having had the one dose since last November, 1933. We are very glad to say that no reaction of any consequence has been heard of, no marked symptoms of any kind have been reported. Of these 614, a total of 530 are under 2 years, and 197 are under 1 year.

There is a signed statement by every

physician in the parish endorsing "the system of universal vaccination against infectious diseases as in effect at the present by our Local Health Unit."

I also represented my parish at the

annual meeting of the State Medical Society. This I tell you to show the manner in which I coöperate with the physicians of the parish. Only 1 case this year and no death.

Oregon to Systematize Health and Welfare

CREATION of a State Department of Public Welfare is recommended in the Report of the Governor's Interim Commission on Health and Welfare which has just been completed and is ready for free distribution. In the new Department would be placed all welfare activities while those relating to public health would be consolidated under the State Board of Health. The Commission recommends that this Board be provided sufficient funds fully to protect the citizens of Oregon.

The Public Welfare Department would have supervision over such matters as child welfare, institutional care, paroles and probations. The Oregon State Board of Public Welfare would consist of seven members, appointed by the Governor. One member would be from the faculty of the School of Social Work of the University of Oregon, and the State Medical Society and the State Bar Association would each recommend one. One term would end each year.

The Commission found that all divisions of the State Board of Health are undermanned, and that with the present financial provision it is impossible to carry on the work adequately. The increased demands for prevention of communicable disease requires the employment of an epidemiologist. Though much overworked, the staffs of the Hygienic Laboratory and the Sanitary Engineering Division have not been able to keep pace with their growing tasks. If the required funds are fur-

nished, it was pointed out, not only could the State Board of Health keep up with this work, but it could also do some intelligent planning to improve sanitary conditions in Oregon.

Recommendations included: That the State Board of Health license hospitals, maternity homes, public health laboratories, food handling establishments, shellfish production, overnight staying places and the industrial camps; fees to be large enough to cover adequate inspection. That venereal disease laws be revised, as the present statutes, besides being unenforceable, do not authorize examination for suspicious cases. The laboratory would be asked to establish free darkfield examination and blood tests for all persons unable to pay, regardless of whether they are indigent. That milk sanitation be transferred to the Health Department, which should coöperate with the State Milk Control Board in setting up and maintaining safeguards.

The Commission failed to reach an agreement on proposed consolidation of the healing arts professions and the personal service group, but suggested that, inasmuch as most of the regulations concern educational qualifications, the Department of Education should have supervision if there is a consolidation. It was added that sanitation should be supervised by the Board of Health, which should pass on all proposed sanitary rules and regulations.—*Weekly Bulletin*, Oregon State Board of Health, Portland, Ore., Dec. 25, 1934.

Control of the Processing of Canned Foods in California*

J. RUSSELL ESTY, PH.D.

*Director of National Cannery Association Western Branch
Laboratories, San Francisco, Calif.*

EXPERIENCE has shown that to preserve foods successfully by canning, all cans should be closed and processed under such conditions that in commercial shipment the ends will retain a concave position under every condition of temperature and altitude that is met. This involves canning the food cold and "exhausting" (heating the food before the container is hermetically sealed), canning the food hot ("precooking") and closing with or without an exhaust, or sealing with mechanical vacuum. To meet the above conditions also implies that the heat treatment given the product after the container is completely and permanently sealed ("process") should be sufficient to prevent the canned food undergoing any change on storage due to the growth of microorganisms surviving the process.

The soundness of canned foods does not necessarily indicate that the product is sterile, *i.e.*, completely devoid of viable organisms. To denote this in contrast to absolute sterility the qualified term "commercially sterile" is generally used by the canning industry. The presence of viable organisms in canned food is not considered significant if their environment is such as to inhibit their growth and multiplication. The ques-

tion is not whether viable organisms are present in the product, but rather is the food wholesome and merchantable?

To require that all canned foods should undergo no change due to microbial activity under any possible commercial storage conditions may be too rigid for general application, since spores of the group known as thermophiles (having an optimum temperature for growth above 100° F.) are generally much more resistant to heat than those of the mesophilic group such as *Cl. botulinum*. In fact, the resistance of many of the thermophilic group is so great that if even a few spores are present in a can it is often difficult to destroy them without rendering the product unmerchantable. In certain products susceptible to this type of spoilage, storage at temperatures above 100° F. for any length of time sometimes results in the development of a small proportion of swelled cans and/or flat sours, but this is not considered significant from a health standpoint.

Whether or not canned foods have been processed to render them commercially sterile in the aforementioned sense, it is universally conceded that they must be "safely" processed. This specifically refers to the effect on the health of the consumer. A "safe process" is one sufficient to destroy bacteria and their toxins that are harmful to health when ingested with food,

* Read before a Joint Session of the Laboratory and Food and Nutrition Sections of the American Public Health Association at the Sixty-third Annual Meeting in Pasadena, Calif., September 3, 1934.

as well as spores of *Cl. botulinum* if the medium is suitable for their development. Extensive research has shown that in products having a pH below 4.5 the germination of *Cl. botulinum* spores is inhibited, and therefore such products can be safely processed in boiling water (212° F.). Practically all the fruits come in this category and the same applies for a very few other products with pH values up to 5.1. However, in general, from our present knowledge, if the food has a pH above 4.5, a process to be considered safe must be sufficient to destroy *Cl. botulinum* spores of maximum heat resistance.

As early as 1920 it was fully realized in California that to control botulism in commercially canned food scientifically established "safe" processes must be used in conjunction with a rigid and continuous inspection of the packing and processing procedures. Canning inspection in California started in 1920 with placing under the jurisdiction of the Bureau of Pure Food and Drugs of the California State Department of Health the sterilization of ripe olives in accordance with the specifications outlined by Dr. K. F. Meyer, Dr. E. C. Dickson and Dr. J. C. Geiger, members of the so-called "Botulism Commission," who were in charge of the investigation financed by the National Cannery Association, Cannery League of California, and California Olive Association.

This was followed on March 24, 1922, by the adoption by the California State Department of Health of a set of definite regulations relative to the processes and fill-in weights for commercially canned spinach.

In September, 1924, the control of the canning procedures was transferred from the Bureau of Pure Food and Drugs to a newly formed Division of Cannery Inspection, which was efficiently organized by M. P. Duffy. As consultant to the California State

Department of Health, Dr. K. F. Meyer was placed in charge of the scientific investigation to prepare process regulations and supervise the technical control of the packs.

On May 23, 1925, Act 428 was passed and approved by the governor, legally creating a Division of Cannery Inspection to regulate the conduct of canneries and provide rules for the proper sanitation of canning plants. This Act specified the inspection of agricultural products—primarily vegetables, and was amended in 1927 to include the supervision of the canning of fish and meat, so that today everyone in California who engages in the commercial canning of agricultural products, fish and fish products, meat and meat products, not subject to inspection by the Bureau of Animal Industry, is required to have a license from the State Department of Public Health, and the operation of the cannery is subject to the rules and regulations of the Cannery Inspection Service. It further provides for the licensing of retort operators who, before a permit is issued, must satisfactorily pass an examination on the fundamentals of steam sterilization and demonstrate their proficiency in the proper manipulation of retorts. Anyone desirous of packing a product liable to botulinum spoilage on which no process has been established must first have a process worked out that will meet the approval of the State Department of Health and then obtain a permit to pack.

The Cannery Inspection is administered by inspectors, who are state civil service employees under Mr. Duffy. Each cannery which packs products subject to inspection is visited daily during the packing season. Some of the important duties of the inspectors are to make a sanitary survey of the cannery; inspect raw material and equipment; calibrate the mercury and recording thermometers and pressure

gauges on the retort; supervise cannery procedures such as fill, exhaust, double seams, process and coding of containers; examine samples of the pack; and in the event of irregularities in canning or processing put the batch involved under restraint and submit samples to a qualified laboratory for examination. Production records are kept and temperature charts prepared as a control on the sterilization time and temperature. On the "Production Record" is noted the number of cans, code mark, time steam turned on, coming-up time, sterilizing time, readings of both mercury thermometers and pressure gauge, and any other pertinent information. Every effort is made to have available for control purposes a set of data giving the complete picture of the technical procedure required to render canned foods safe.

The coding of cans is an important provision in the regulations. By descriptive marks the inspector or food official can promptly identify a batch of questionable quality and remove it from the consumer's market without being forced to quarantine the seasonal output of a packing plant. In the case of a number of products, notably ripe olives, spinach, sardines and tuna, batch coding is specified; *i.e.*, all cans in a given retort are stamped with the same mark to differentiate them from those in other retorts. This is the smallest unit coded alike at the present time. Coding of other products may be restricted to segregating morning and afternoon packs.

For a number of products, such as artichokes and chili peppers, which in their natural condition are rendered unmerchantable by sterilizing processes, procedures are employed to acidify the product to a pH of at least 4.5.

Whereas the control of foods processed under pressure is by means of checking temperature charts, for acidified products titrations of periodic

samples of blanching and brining solutions are made. The fill of cans is also check-weighed daily, and at regular intervals electrometric pH determinations are made on samples of the finished product.

In all cases production records are carefully scrutinized. All food products packed under this inspection must be held by the canner until released by an inspector who, if the records show that all requirements have been met, issues a release order for shipment.

Lots that are restrained are set aside by the inspector, and representative samples are subjected to laboratory tests for sterility or, in the event of spoilage, to determine the cause of the abnormal condition. The number of cans submitted depends upon the nature of the defects or irregularities. When the laboratory findings are completed, and after due consideration of all the available data, the disposition of quarantined lots is decided by the Consulting Bacteriologist to the State Department. In the event of spoilage due to under-sterilization, all the cans involved are usually destroyed.

With this inspection service cases of under-sterilization in the products under surveillance have become rare. In fact, only a relatively insignificant number of the cans packed under inspection are placed under restraint for any cause, yet through this supervision an appreciable number of errors in processing is detected each year, which would otherwise pass unnoticed. Many of these defects are extremely slight and after investigation are found not to have affected the wholesomeness of the product.

At the present time the inspection service is supervising over 50 products, on which definite process regulations have been adopted by the California State Department of Health. The processes recommended for these products have been based upon a standardized procedure involving—

1. A study of the rate of penetration of heat in different sized containers under laboratory and factory conditions with variable filling-in weights.

2. Heat resistance of spoilage organisms, including *Cl. botulinum* spores.

3. Experimental packs of cans inoculated with a definite number of spores of suitable test organisms standardized to have a heat resistance comparable to that of *Cl. botulinum*. Recommended processes are finally obtained by applying a factor of safety to the heat treatment found to sterilize the product in the inoculated cans.

In this work the research laboratories connected with the canning industry have actively coöperated, and our present knowledge of processing non-acid foods is the combined experience accumulated during a period of over 15 years of continuous experimental work. The processes for non-acid foods officially used in California are those published in *N. C. A. Bulletin* 26-L revised, which were adopted by the Directors of the National Cannery Association and recommended for general use throughout the country. The collaborative studies are still in progress and as more experimental data become available the adequacy of processes for products liable to botulinum spoilage becomes more firmly established.

To indicate the scope of the laboratory in the technical control of the pack: from January 1, 1928, to July 2, 1934, samples from 370 restrained lots of vegetables and 237 specialty products have been examined. From each batch restrained a minimum of 24 cans, and frequently as many as several hundred, are tested. In addition to these a large number of samples of fish and fish products have been studied. The processing of 275 products, many of which were specialties of a more or less similar composition, has also been investigated. In some instances it was found impracticable to can safely certain products according to the methods contemplated, and packers being convinced of this abandoned the project.

However, in most cases proper processing methods were developed.

To determine whether or not the canned contents from restrained lots are "commercially sterile" no one procedure is applicable to all canned foods. Usually it is first necessary to incubate representative cans, and the time and temperature of incubation are more or less arbitrary, depending upon the types of organisms present and the particular class of product to be examined. In some cases it is necessary to use a rather long period because of slowness of growth of certain facultative thermophiles at temperatures below the optimum for development, or delayed germination of certain spore-bearing anaerobes such as *Cl. botulinum*. In relatively unfavorable mediums it might be necessary to store cans for an indefinite period. As a routine procedure to establish the commercial sterility of products with a pH above 4.5 cans should be incubated for at least 4 weeks at 98° F. For foods susceptible to thermophilic spoilage cans should be stored for at least 2 weeks at 98° F., followed by 10 days at 125° F. In the case of products with a pH below 4.5 it may be advisable to incubate at about 80° F. and also at 98° F. After the cans have been incubated for a sufficient time to permit spoilage organisms, if present, to develop, the contents in normal appearing cans are examined with respect to pH, general appearance and odor. If abnormality is detected, further tests may be necessary to confirm the observation. In the event spoilage is indicated from an abnormal external appearance of the can, every effort is made to ascertain the cause.

The technic of bacteriologically examining a canned product is relatively simple in so far as aseptically transferring material to enrichment mediums and other important details are concerned, but to interpret properly the results obtained requires careful analysis

and judgment based upon experience. Whether or not the organisms isolated are actually spoilage types; the significance of hydrogen springers or of thermophilic organisms; the absence of, or the failure to recover organisms in case of bacterial spoilage; the heat resistance of the spoilage organisms recovered; and a number of other questions are involved. Not infrequently one is unable to recover certain types of organisms if the cans are not cultured shortly after spoilage has developed, or even to see bacterial cells by the microscopic examination of stained or unstained preparations. This is particularly true of slow developing thermophiles that die and disintegrate about as rapidly as they develop. In acid products especially, dormant sporing organisms may develop on enrichment, but as growth is inhibited at the low pH their presence has no significance.

The bacteriological findings are only one important link in the chain of evidence necessary to be considered in a proper diagnosis of the cause of spoilage. These should be analyzed in connection with the condition of the can, factory operations, previous experience with the process, extent and amount of spoilage, *i.e.*, whether or not it is general, confined to one day or one line, or whether it is more or less spotted through a given period, and also whether it is confined to lots shipped to certain localities. The cans should be tested for obvious defects, such as perforations or faulty closure, and the interior examined for corrosion effects. In the case of bulged cans the gas in the headspace should be analyzed for this gives presumptive evidence as to whether or not the swelling is bacteriological or due to chemical action. For comparative purposes representative normal cans should be studied.

The possibility of an analyst making a wrong diagnosis, especially if all the facts are not available or are not con-

sidered, may be illustrated by the following example, which is typical of problems that are continually being met in dealing with spoiled canned foods.

An analyst receives swelled cans of pears for examination. He cultures these cans according to a certain technic on certain media and incubates the cultures at a certain temperature for so many days, during which time they remain sterile. The acidity of the product is abnormally high (low pH). Nothing definite is observed in the stained preparations examined microscopically. The analyst, with such meager information, is naturally puzzled regarding the cause of the swells.

In dealing with such a case there are many possibilities to be considered. First, is the gas hydrogen or carbon dioxide or a mixture of both? If hydrogen, is this due (1) to chemical action of the product with the container, or (2) to a hydrogen-producing bacterium, or (3) to flat sour spoilage with subsequent hydrogen production through chemical action due to the lowering of the pH of the fruit juice, or (4) to bacterial growth in the fruit before cooking, with lowering of pH and subsequent development of hydrogen? Data on the type and extent of spoilage should also be considered. If both hydrogen and carbon dioxide are present, is the spoilage due to under-sterilization or to leaky seams? Expert judgment as to the condition of the double seams and a knowledge of the canning and processing operations are required to determine the significance of these factors.

Another condition that a food bacteriologist may encounter in his study of spoiled canned foods is the presence of non-heat-resistant organisms in vegetable and meat products in cans having satisfactory seams, or of acid producing organisms in swelled cans. Is the spoilage due to under-sterilization or leakage of bacteria subsequent to

processing? In such cases it is impossible from the bacteriological findings alone to reach a definite conclusion; whereas with a knowledge of canning procedures the trouble is more readily explained.

The subject of spoilage in canned foods is a very complex one, and this becomes more apparent the longer one works in this field. In view of the great number of canned foods, varying in their chemical composition and acidity (pH ranging from below 3.0 to

above 8.0), and the many types of organisms that can grow and produce changes, the bacteriological examination of every food, and often of a given lot of a particular product, has to be considered as a separate problem to be studied in the light of the whole previous history of the case. With the ever changing technic of canning procedures, the problems become so complex that only experienced analysts in constant contact with actual canning operations can be expected to solve them.

Smallpox Diminishing

THERE was less smallpox in the United States and Canada in 1933 than ever before, and if we may judge by the records for 7 months of 1934, there will be a further drop this year, in the opinion of the *Statistical Bulletin* of the Metropolitan Life Insurance Company. These 7 months not only show a new low record for the period, but report less than one-tenth the number of only 4 years ago. The fight on smallpox seems nearly won.

Some states, however, still have a bad record, for 4,589, or 75 per cent, of the 6,122 cases reported by 46 states occurred in 12 states that contain only one-fifth of the country's population.* Popular sentiment in these states is against vaccination.

Contrast with these, 10 other states † and the District of Columbia, along the Atlantic seaboard, which had only 4 cases of smallpox in 1933, and only 809 in the last three years.

* The 12 states with high smallpox records are California, Colorado, Idaho, Oregon, Iowa, Montana, Nevada, Oklahoma, Texas, Utah, Washington, and Wisconsin.

† The 10 states with low records are Delaware, Florida, Maine, Maryland, Massachusetts, New Hampshire, New Jersey, New York, Pennsylvania, and Rhode Island.

There is no reason to doubt that this fine record could be duplicated by the rest of the country.

In continental Europe, where compulsory vaccination is generally accepted and practised, smallpox has practically disappeared from all of the countries, excepting Russia and the Iberian Peninsula. In 1931 there was not a single case of smallpox reported in Belgium, Bulgaria, Scotland, Germany, Italy, Luxembourg, Norway, Sweden, Switzerland, and Yugoslavia. Only 1 case each was reported in the Netherlands and Latvia, 5 in Finland, 12 in Greece, 13 in Roumania, and 14 in Poland. France, with a population of over 40 millions, reported only 162 cases.

In England and Wales, on the contrary, where since 1907 "conscientious objectors" have been exempt from compliance with the vaccination laws, the incidence of smallpox has reached such proportions that in 1931 there were reported 5,665 cases, a number far in excess of the total number of cases reported by the whole of continental Europe, excluding Russia.—*New York State J. Med.*, 34, 23:1021 (Dec. 1), 1934.

Experiments on the Purification of Creamery and Packing-House Wastes*

MAX LEVINE, PH.D., F.A.P.H.A.

*Professor of Bacteriology, and Bacteriologist, Engineering Experiment
Station Iowa State College, Ames, Iowa*

IN the course of some small scale experiments on the purification of creamery and packing-house wastes, several observations were made which might be of interest and possibly of practical significance to those engaged with the problems of waste disposal. The time available does not permit elaboration. The various items will be but briefly considered.

EXPERIMENTS WITH CREAMERY WASTES

Several observations on the effect of bottom ventilation and dosing cycle on purification are considered particularly interesting.

Effect of Bottom Ventilation—Skim milk solutions were applied to a small filter 2' square and 6' deep, at a rate of 800,000 gal. per acre per day for about 14 hr. daily.† The filter was constructed of metal and provided with a hopper bottom which terminated in a water seal trap (Figure I). This hopper bottom was provided with air ports so that the filter could be operated either with or without bottom ventilation. The filling material consisted of coarse washed cinders, or rather clinkers, retained on a screen with $\frac{1}{2}$ "

openings. The results are detailed in a recent Bulletin¹ of restricted circulation. Figure II, taken from that publication, shows clearly that a very high degree of purification was effected when the air ports were open, permitting adequate and thorough bottom ventilation (wastes of about 1,000 p.p.m. B.O.D. were reduced to effluents of about 10 p.p.m. B.O.D.), but that closing these ports resulted in very rapid deterioration of the purifying efficiency of the apparatus. With bottom ventilation eliminated, the filter clogged badly, and this condition was not remedied by merely opening the air ports; the clogging material had to be washed out to effect relief.

Effect of Dosing Cycle—One filter as above, and another filled with $1\frac{1}{2}$ " to $3\frac{1}{2}$ " rock in place of the cinders, but with the hopper bottoms removed, were dosed simultaneously with a skim milk solution at a constant rate of about 600,000 gal. per acre per day, but the dosing cycles were varied in the range of approximately $2\frac{1}{2}$ min. to 22 min. The purifications effected as indicated by B.O.D. reductions are shown in Table I.

It appears that the dosing cycle had no significant influence on the purification effected by the cinders but that with the coarser rock as a filling material, the short dosing cycle was distinctly preferable, reductions of 90.5

* Read at a Joint Session of the Laboratory and Public Health Engineering Sections of the American Public Health Association at the Sixty-third Annual Meeting in Pasadena, Calif., September 4, 1934.

† Designed by H. N. Jenks, who was associated as a consultant on some of the experiments at Iowa State College.

TABLE I

EFFECT OF DOSING CYCLE AND NATURE OF FILLING MATERIAL ON PURIFICATION OF CREAMERY WASTES

Dosing Cycle		2½ Min.	5-7 Min.	10-12 Min.	20-22 Min.
		B.O.D. (5 days 20° C.)			
Applied Waste		1,010 (± 113)	1,020 (± 40)	975 (± 200)	1,030 (± 100)
Eff.	Cinder	4 (± 0.5)	5 (± 2)	10 (± 8)	8 (± 4)
	Rock	96 (± 23)	94 (± 27)	127 (± 31)	227 (± 54)
Per cent Reduction	Cinder	99.6	99.5	99.0	99.2
	Rock	90.5	90.7	87.0	78.0

per cent, 87.0 per cent and 78.0 per cent being obtained with the 2½ min., 10-12 min. and 20-22 min. dosing cycles respectively.

It was also observed that whereas the dosing cycle had no appreciable effect on the fluctuation in the rate of run-off of the effluent from the cinder filter, the

rate of run-off from the coarse rock filter was very markedly affected as is shown in Figure III. The run-off cycle is very significant from the standpoint of sampling and it probably also affects the efficiency of post-filtration sedimentation. Thus, effluents with B.O.D.'s as low as 24, or as high as

428 could be obtained, depending on the point in the effluent cycle at which the sample was collected. In the experiments reported here (which are considered of a preliminary nature and are being studied further) this sampling error was eliminated by including in the sample all of the effluent during a complete cycle.

EXPERIMENTS WITH PACKING-HOUSE WASTES

Some studies were made on a small scale to ascertain: (1) whether the high

salt content precluded the use of the activated sludge process for treating packing-house wastes; (2) the effect of aeration of a deep trickling filter; and (3) the feasibility of employing double filtration (the first filter being decloggable by back-washing) for purification of packing-house wastes.

Observations with the Activated Sludge Process—An activated sludge plant was in existence at Mason City, Iowa, for treatment of packing-house wastes. The purification effected was not satisfactory (45–55 per cent) and rumors were current that the poor results were due to the salt (1,200 to 1,500 p.p.m.) present as sodium chloride. This conception was so prevalent that it was felt necessary to demonstrate that this was not the cause of the difficulty.

An activated sludge was prepared by circulation of packing-house waste in an experimental stream-flow aeration device (Figure IV) which has been previously described by Jenks and Levine.² The tank was then charged with an 8 per cent and 20 per cent pickle brine. The results are shown in Table II, from which it is apparent that the activated sludge process functioned effectively even in the presence of 20,000 p.p.m. NaCl when operated on a fill and draw basis. The poor efficiency of the continuous flow activated sludge plant previously referred to could not be due to the salt content of the waste which was only about 1,200 p.p.m., and is attributed to the very excessive fluctuations in the concentration of the wastes reaching the purification plant.

Purification by Double Filtration (Aerated Filter)—Packing-house waste which had been settled for about 1½ hr. was applied to a filter 3½' square, and 10' deep at a rate of 7×10^6 gal. per acre per day for a period of 6 months. The filling material consisted of 1 to 2½" red granite. The filter

FIGURE II—Effect of bottom ventilation of trickling filter B on the biochemical oxygen demand and reaction of the effluent

was constantly aerated through a perforated grid on its bottom.

The purification effected was very satisfactory (about 40 per cent B.O.D.) considering the high rate of application,

and there was no evidence of serious clogging. The effluent from this aerated filter was settled in a small Imhoff tank and then applied to a cinder or coarse gravel filter, 3' square and 8' deep, at

a rate of 3×10^6 gal. per acre per day. The results are summarized in Table III.

It may be seen that a very high degree of purification was effected. Filtration at 7×10^6 on 10' of aerated coarse rock effected a reduction of

40.9 per cent in B.O.D. and 54 per cent in organic nitrogen, but the ammonia increased considerably. Sedimentation of this effluent increased the B.O.D. removal to 49.9 per cent and the organic nitrogen removal to 71 per

† Increase.

cent. Further treatment of this partially purified and settled waste by application onto cinders and gravel filters at 3×10^6 gal. per acre per day effected over-all reduction in B.O.D. of 96.8 per cent and 93.9 per cent respectively, and correspondingly high reduction in organic nitrogen (95.0 and 90.5 per cent). Nitrification was particularly good, 40 to 44 p.p.m. of nitrates being present in the effluents which consequently showed stabilities of over 90 per cent.

Purification by Double Filtration (Washable Filter)—A settled packing-house waste was applied to a shallow cinder filter, 3' square and 3' deep, at a rate of 4×10^6 m. gal. per acre per day, and the effluent, after resettling in an Imhoff tank, was applied to a filter

3' square and 8' deep, containing 1 to 3" dolomite, at a rate of 3×10^6 gal. per acre per day. The primary or cinder filter was so constructed that it could be washed free of clogging materials by back washing with water and agitation with air.

The results, for a period of about 3 months, are shown in Table IV. The waste during the experiments (March to June) was not as strong as that employed in the aerated filter studies. The purification effected was very satisfactory.

Filtration through 3' of cinders at 4×10^6 gal. per acre per day effected reduction of 56.5 per cent in B.O.D. and 34.7 organic nitrogen. These reductions were increased to 59.2 per cent and 51.1 per cent for B.O.D. and

organic nitrogen respectively, by sedimentation in a small Imhoff tank. Further treatment of the effluent from the Imhoff tank on an 8' dolomite filter, 1"-3" filling material, at 3×10^6 gal. per acre per day effected over-all reduction of 93.2 per cent in B.O.D. and 83.7 per cent organic nitrogen. Nitrification was very good, the effluents contained an average of 20.8 p.p.m. of nitrates and were stable (relative stability over 90 per cent).

Purification of Packing-House Wastes by Double Filtration—In 1929 a plant designed on the principle of the washable filter just described was put into operation at the Jacob E. Decker Packing Company at Mason City, Iowa. It consists of a modified Dorr settling tank with $1\frac{1}{2}$ to 2 hr. sedimentation, followed by treatment on $\frac{1}{4}$ acre of a shallow washable filter, at about 3×10^6 to 4×10^6 gal. per acre per day, and the effluent from this filter, after settling for $1\frac{1}{2}$ to 2 hr., is applied to a dolomite filter $\frac{1}{2}$ acre in area and 8' deep at 1.5×10^6 to 2×10^6 gal. per acre per day, the filter effluent being subjected to final sedimentation in a

modified Dorr clarifier before discharge into the stream. The primary washable filter which at first contained cinders, was later changed to $\frac{1}{2}$ " to 1" dolomite. The secondary, deep 8' filter, was filled with 1" to 3" dolomite.

The plant was designed to handle 750,000 gal. per day, with a maximum rate of flow of 1,000,000 gal. per day through the purification plant, during a part of the day, and it was anticipated that with a maximum initial B.O.D. of 1,000 p.p.m. a reduction of 85 to 90 per cent would be obtained, *i.e.*, the maximum reduction anticipated, was 5,300 to 5,600 lb. B.O.D. per day.

The results for the year 1933 are summarized in Table V. The effluent from the first settling tank, which is applied to the washable filter, is referred to as the "primary clarifier"; the effluent from the washable filter after settling, which constitutes the waste applied to the deep filter, as the "intermediate clarifier"; and the effluent from the final filter, after settling, as the "final clarifier" in Table V.

The average volume of sewage treated during the year 1933 was about

No. of samples for B. O. D.	201	197	198	202

Over-all per cent reduction

Org. N.	—	34.7	63.8	92
NH ₃	—	—	—	24.7
O ₂ Cons.	—	31.1	58.6	72.7
O ₂ Dem.	—	29.0	62.8	94.3

600,000 gal. per day and the maximum volume 900,000 gal. per day. The average B.O.D. of the applied waste was $1,437 \pm 404$, the minimum for any one day 650, and the maximum 3,850. The purification effected by the various portions of the sewage treatment plant are also shown in Table V. Over-all reduction of 92 per cent organic nitrogen, only 29.7 per cent ammonia, 72.7 per cent oxygen consumed and 94.3 per cent oxygen demand were effected.

A more detailed idea of the workings of the various portions of the plant may be obtained by examining Figures V and VI, from which it will be noted that 50 per cent of the applied wastes had B.O.D.'s of between 700 and 1,400 p.p.m., while 50 per cent of the final effluents showed B.O.D.'s between about 20 and 56 p.p.m. The next higher 30

per cent of the samples of applied wastes had B.O.D.'s between 1,400 and 1,800 p.p.m. and the effluents between 56 and 110 p.p.m. B.O.D. Finally, 20 per cent of the raw wastes had B.O.D.'s of over 1,800 (2 per cent over 2,500) and 20 per cent of the effluents were over 110 p.p.m. (2 per cent over 250 p.p.m.) B.O.D.

The per cent reduction of B.O.D. is a reasonable figure for comparing the efficiency of the various portions of the plant on any given day, or for different days, if the volume and concentration of applied wastes are constant, but in view of the fluctuation in volume of waste treated from day to day, analysis on the basis of the total pounds of B.O.D. removed is probably a more dependable measure of the plant efficiency. An analysis of the efficiency of

Over-all	—	37	65.8	95.2

FIGURE VI—Purification of packing-house wastes by settling and filtration

the plant on this basis is shown in Table VI.

In short, sedimentation for about $1\frac{1}{2}$ hr. effected a reduction of 37 per cent B.O.D. Treatment of the effluent on 3' of rock at an average rate of 2.4×10^6 gal. per acre per day followed by settling, reduced the B.O.D. of the applied effluent by 45.9 per cent or an over-all reduction of 65.8 per cent. Finally, application of this settled shallow filter effluent on 8' of coarse dolomite at an average rate of 1.2×10^6 gal. per acre per day and settling resulted in a further reduction of 81.8 per cent in B.O.D. of the applied waste or an over-all reduction of 95.2 per cent.

The over-all removal of B.O.D. by filtering and sedimentation of filter effluents (exclusive of primary sedimentation of the raw waste before application to the filters), was 633 lb. per acre-foot.

SUMMARY

Data are presented on some experi-

ments in the treatment of creamery and packing-house wastes and results of a full size plant for treating packing-house wastes, which indicate that the full capacities of trickling filters are not

generally utilized in treatment of domestic sewage.

DISCUSSION

CHARLES GILMAN HYDE, F.A.P.H.A.

Professor of Sanitary Engineering, University of California, Berkeley, Calif.

IN this paper the author has made a valuable contribution to the art of industrial wastes treatment. The paper contains not only a wealth of information but much suggestive material which offers food for thought. For instance, the effect of excessive and greatly varying loads upon activated sludge plants is referred to and indicates a possible explanation of difficulties experienced at times with that type of plant.

At least 4 very interesting phases of the general subject are presented:

1. The basic laboratory experiments covering two distinctly different methods of treatment of very strong industrial wastes: (a) the activated sludge process on the so-called stream-flow principle; (b) trickling filtration.

2. The model plant experiments utilizing two-stage trickling filtration and developing apparently authentic results.

3. The application of the procedure of the model plant to full scale in treating a relatively large volume of wastes of extreme variability in composition and of extraordinary strength or concentration.

4. The operation of the practical, full scale plant through a 5 year period and the presentation of the results obtained during the last or 5th complete year of operation.

Diagrams V and VI are of particular interest as exhibiting methods of exposition of analytical results. Diagram VI is especially noteworthy in that it shows at a glance the performance of the plant with reference to B.O.D. removal. The spread of the analytical determinations representing the performance of each stage of the treatment process is graphically shown to great advantage.

To an increasing extent industrial wastes are attracting the attention of sanitary engineers and laboratory technicians both from the standpoint of possible salvage and that of treatment to prevent excessive stream pollution and nuisances.

It is refreshing to have, as in this paper, a review of the results actually achieved by a full scale plant which has been operated through a period of several years and not merely one which has just been designed with the fervent hope of successful accomplishments. Engineering literature is replete with prophecies but too frequently silent or arid with respect to actual realizations and accomplishments.

Unfortunately, where biological agencies play a significant part in the ultimate results, the "model law" is not always apparent; and perhaps never to the extent that it is in the field of structural and hydraulic experimentation. For this reason, while "bottle" experiments have their indisputable place, the results secured therewith cannot be applied with assurance to full scale plants. Batch treatment is not to be compared with variable flow treatment. The author wisely supplemented bottle or batch experiments with flow experiments through a model plant of such size as to yield reasonably authentic results which could be extrapolated to the conditions of a full scale plant. This procedure is particularly desirable,

even necessary, when the method of treatment is unique, as in the case in question.

Standard practice in trickling filtration makes use of coarse grained aggregates rather than fine grained materials such as sand or cinders. The author has clearly shown the advantage of short dosing periods or cycles where coarse rock is employed in trickling filters, and especially when these are subjected to heavy and widely varying loads. The importance of bottom ventilation under such conditions has been clearly demonstrated.

The author is to be congratulated in

that he has developed a type of treatment applicable to enormously variable and extremely heavy loadings and one which, on the basis of B.O.D. removal, seems to be relatively cheap in installation and operating costs.

The author does not describe the design and construction features of the working plant whose operating results he so interestingly and instructively sets forth. It is very desirable that this be done and it is hoped that in the near future he, perhaps in collaboration with the designing engineers, will prepare an adequate description of that plant from the design and construction standpoints.

Health Statistics of New York

INFANT mortality, tuberculosis deaths and cases, and other health statistics are now compiled regularly for each health area in the City of New York by the Health Department. Various welfare organizations are at work collecting information concerning juvenile delinquency, services rendered by philanthropic agencies, residence of patients discharged from hospitals, and other data, all on the basis of residence in health areas.

In addition to the statistics given in *Heads of Families*, and other volumes in the series of studies of neighborhood statistics, information is available in the Research Bureau of the Welfare Council of New York City, 122 East 22 Street,

New York, on the smaller divisions which make up the health areas. These smaller divisions are census tracts and for them the U. S. Census Bureau compiles the statistics which form the source material of the Welfare Council studies. Each census tract is approximately 40 acres in area and there are some 3,400 tracts in New York City.

Other studies of neighborhood statistics which contain information regarding every health area in the five boroughs of New York are *Population in Health Areas*, which gives the population by age groups and by color, nativity, parentage, and sex, and *Homes by Tenure and Value or Monthly Rental*.

A Nutritional Survey of Forty-five Hundred Children on Relief*

J. C. GEIGER, M.D., F.A.P.H.A., AND PAUL S. BARRETT, M.D.

*Director of Public Health; and Director, Bureau of Child Hygiene,
Department of Public Health, San Francisco, Calif.*

LESS than a year ago the Children's Bureau of Washington, D.C., called a conference to consider the reported increase in malnutrition due to the depression.

This reported increase was based on studies from New York City, Massachusetts rural regions, and a Philadelphia relief group, notwithstanding the fact that a number of public health workers had called attention to the lack of objective standards of nutrition. Others had emphasized the fact that current morbidity statistics did not point to widespread emergency and the writer in a letter dated September 27, 1933, addressed to a member of the Child Health Recovery Committee wrote:

In conclusion, I might say that it is the opinion of all the workers in the Department that the nutrition of San Francisco children has not materially suffered, and I even could go so far as to say that never before have the families on relief been under such competent medical supervision. Malnutrition may exist in the isolated case of a child whose family is too proud to ask for relief, or in that group of transients whose movements are difficult to check and who are not under adequate supervision, and who are part of the vexatious nonresident problem.

On March 1, 1934, the Emergency Relief Committee of San Francisco changed its policy in administering relief. Prior to that date relief was on a commissary basis, that is, boxes of food were distributed to families, fresh milk was delivered, and in addition a weekly stipend was allowed for the purchase of fresh meat. Beginning the first of March this system was changed to a cash relief basis for a trial period of 6 months. Families on relief received a weekly check with which they were to purchase their own food supply. It was felt by the committee that a survey of the nutritional status of the children who had been on this commissary system for the periods varying from 6 months to 2 years would show whether or not it had resulted in maintaining the nutrition of the recipients of relief. Upon their request the Department of Public Health undertook a systematic measurement and examination of the children of all families on relief.

Until recently standards of nutrition have been extremely unsatisfactory. Estimates of deviation from normal based on a specific weight for age and height are notoriously inaccurate. The A.C.H. Index, recently developed by Franzen & Palmer,¹ gives a satisfactory standard of nutritional status. This index is based on 3 measurements, arm

* Read before the Child Hygiene Section of the American Public Health Association at the Sixty-third Annual Meeting in Pasadena, Calif., September 6, 1934.

girth (A), chest depth (C), and hip width (H). These measurements subjected to two additions, a subtraction and reference to a table, serve to identify children with a marked discrepancy between the amount of soft tissue (muscle and fat) and the amount of bony tissue (skeletal build). Previously to the publication of this work, Pryor & Stolz² had submitted a somewhat similar plan to estimate normal weight, using a length-width index based on the height of the child and the width of the iliac crests. This length-width index of body build is used not only to designate types of build but also as a basis for weight prediction, a feature not present in the A.C.H. Index. The bi-iliac diameter divided by the height times 100 gives the length-width index and is a measure of the relative width of the body. The bi-iliac diameter can be measured more accurately than chest width or shoulder width because it is not affected by respiratory movements or changes in posture. This greater accuracy of the bi-iliac diameter can be demonstrated when two observers measure the same children.

Various complicated indices of body build have been advocated, each involving several body measurements of girths and diameters. A comparison of these measurements with the single bi-iliac

diameter, each in percentage of height, shows the same classification of body build for each system.

The bi-iliac method was the method of choice because it was more constant, more accurately and more easily measured, and yielded the same results. An added feature was that a control group of California children was available by this system. This control group included 2,000 public school children in San Francisco, Oakland, and San Mateo, 700 clinic patients at University of California Hospital, 300 at Children's Hospital, 300 private school boys, and 60 children in a special survey in Berkeley. The method of procedure was as follows:

Four regional centers were established, one in the main building of the Health Department and two in branch offices in the Mission and Alemany districts, the fourth center was in the North Beach section, the space being donated by the Telegraph Hill Neighborhood Association. Physicians to conduct the survey were furnished by the Emergency Relief Committee. Nurses and clerical force were obtained through the C.W.S.

The Emergency Relief Committee then set about getting the children to appear for examination, which was done through the Relief Visitors who were

Visitors to determine which children did not report and a second post-card (Figure II) was sent to them urging attendance. The response was excellent, over 4,500 children reporting for

examination in 7 weeks. The interest and coöperation of the public schools was secured, and a notice was printed in the *School Superintendent's Bulletin* requesting that principals excuse these

children from school upon presentation of their card from the Relief Committee.

After registration, the child was undressed and his weight and height were recorded on the physical examination card (Figure III). He was then presented to the physician who measured the bi-iliac diameter and proceeded to make a careful physical examination including an estimate of the posture and muscle tone expressed as "Good," "Fair," or "Poor." The normal weight and variation from the normal were not calculated at time of the examination. All physical defects found were recorded, and when necessary full notations were made on the reverse side of the child's card describing significant findings. The parent was given a slip of paper (Table IV) on which was indicated the need for medical attention, and was directed to report to the Relief Visitor on whom the responsibility for arranging for such attention had been placed. The Relief Visitor had also been given a duplicate of the form for parents and so was in a position to check on whether or not the physician's directions were being followed. Although the primary objective of the survey was to secure accurate data on the nutritional status of the San Francisco children on relief, the opportunity to do an intensive health promotion project was in this way not lost sight of.

For the purpose of tabulating results the children were divided into two age groups, the preschool group under 6 years and the school group, 6 to 16 years. The defects found among the preschool group were noticeably few. Of 840 children, only 10 were found with extreme malnutrition, estimated clinically. Eight apparently were found in the estimation of nutrition by the measurement method (Table III), corroborating the subjective estimate made by the physician at the time of examination. Without exception these children had never attended a Child

Welfare Conference and their feeding and hygienic regimen had at no time been under the direction of a physician. The remainder of the preschool group was remarkably free from defects. Among the school group the outstanding defects paralleled those found in routine school examinations, teeth and tonsils leading. The presence or absence of defects appeared to have no relation to nutritional status. An interesting sidelight on the examinations was that when severe physical defects of heart or lung were reported, check with the school health records invariably revealed identical notations and, in most cases, the child was found to be already under regular medical supervision. A tabulated list of the defects found by districts for each age group is given in Tables I and II.

After the examinations were completed the normal weights were estimated according to the tables furnished by Pryor & Stolz² and the variation from the normal calculated by taking

the difference between actual and normal weight. The number and percentage of the total group and the percentage of their variation from the normal is shown in Tables III and IV. This group compared with a control group is graphically shown in charts (Figures V and VI).

DISCUSSION

The interpretation of these figures and the conclusions to be drawn from them are at present a subject for discussion.

In the school group (Figure VI) it is possible to say that 11 per cent are 10 per cent or more underweight, and in the preschool group (Figure V) less than 5 per cent are in this classification. Comparing this with the control group the figures are 13 per cent and 8 per cent respectively. Certainly it would seem logical to draw the conclusion that underweight for body build was not more, or even as prevalent among the relief group as among the control group.

Referring to the graphic chart of the school group (Figure VI) the widest

variation occurs with the children 5 per cent underweight, a variation of 7 per cent rapidly converging to the point 5 per cent overweight. From that point on to the extreme overweight the relief group is convincingly in the majority.

With even a conservative interpretation of these findings it must be admitted that the nutritional status of children who had been on commissary relief compare very favorably with a normal or even more privileged group in the community.

The homographic aspect of the preschool group chart needs but little comment. However, it would seem to refute, for San Francisco at least, the frequently repeated charge that the preschool age was the neglected age, at least as far as nutrition was concerned. When we consider, however, that the

vast majority of these children were registered in well baby conferences throughout the city the result is not surprising.

Six months ago the families of these children went on cash relief. It would seem highly desirable to repeat this survey, beginning if possible soon after

FIGURE VI

the first of September. The comparison of the results of the two examinations would be extremely valuable although the time is perhaps too short to judge adequately the advantages or disadvantages of the cash system. In addition a second examination would afford an opportunity for the comparison of weights in individual children which would undoubtedly be of considerable value in estimating the trend of growth and nutrition of the child.

Other considerations include the follow-up work for correction of remedial defects and the selection of special children whose wide variation from the normal height-weight ratio would single them out for special study.

If for purposes of discussion the length-width index as described is to some degree a measure of nutritional status, it would seem advisable to conduct similar surveys in various parts of the country.

The objection relative to expense raised editorially in the *J.A.M.A.*³ a year ago is no longer a valid one. With the F.E.R.A. in operation public health officials are continuously besieged to provide work projects for the professional groups. What more profitable way to employ our needy professional brothers and sisters than by securing a cross-section of the physical condition of the children throughout the country? The use of a standard system of measuring is of course advisable for purposes of comparison. The methods used at present to arrive at a diagnosis of malnutrition are almost as numerous as the workers.

Until a more satisfactory standard is developed the simple procedure described is recommended as the one of choice. Its advantage over other methods, in addition to its simplicity,

is that it can be used as a basis for weight prediction.

While it is admitted that malnutrition has never been confined to the poor, a survey of relief groups may do much to counteract some of the hysteria and even panic created by well meaning but uninformed self-styled nutritionists by their dismal picture of what was happening to our child population in the depression.

Finally it must always be borne in mind that malnutrition is a symptom and not a clinical entity. Without a well planned follow-up the mere collection of statistics may indeed be called an idle gesture.

SUMMARY

1. A change in the plan of administering relief in San Francisco made it advisable to estimate the nutritional status of the children who had been receiving aid.
2. A length-width index of nutrition was chosen as the method of selection.
3. The technic of conducting the survey is described.
4. A statistical analysis of the findings is presented.
5. Recommendations for a continuation of the study are made.

CONCLUSION

1. The relief program prior to March 1, 1934, was adequate as far as the nutritional status of the children measured by a length-width index, is concerned.
2. The aspect of health education by the physical examination for the discovery of defects was not neglected.
3. There is need for a second and third examination at intervals of 6 months.
4. Similar undertakings would be advisable throughout the country using F.E.R.A. funds.

City Health Department Clinics*

Activities of Public Health Nurses in Case Finding and Case Holding in Relation to Syphilis

RACHEL K. MILLER, R.N.

Health Department, Oakland, Calif.

CLINICS for the treatment of syphilis abound today, and yet, either there are not enough of them or most of those which do exist are not properly administered. The incidence of syphilis is not appreciably reduced. This presents a definite challenge to health departments to formulate and administer improved programs. Case finding methods should bring in a much larger percentage of early cases for diagnosis, and case holding systems should keep these cases for treatment and observation until they have been symptom free over a long period of time.

The first element of importance perhaps is to eliminate fear and establish confidence. When people have faith and hope and know the source from which help comes, they besiege the giver and have neither to be sought nor held. The newly infected person who has been taught to recognize symptoms and can feel that treatment will be given without stigma, will be more liable to ask for treatment and come for it. Everyone who comes to the clinic is motivated by hope, and most are not only ill but are dwarfed by wounded pride and thwarted ambition. Everyone

who leaves the clinic should go out with confidence in its ability to help.

Michael Davis in his book *Clinics, Hospitals and Health Centers* makes the following statement: "The most important element in effective case control is the work done *while the patient is in the clinic*, not the correspondence or even the home visits which come afterward." Good service to the patient in the clinic, particularly at the first visit, is the most important single factor.

The public health nurse has a unique part to play in making a clinic a success. Hoping for results in a syphilis control program, she has acquired an understanding of the disease, its etiology, the modes of transmission, the usual methods of diagnosis and treatment, and the common reactions. She has also cultivated a sensitiveness to individual needs, especially in relation to mental and social complexities and twisted attitudes. Moreover, she has acquainted herself with the social welfare agencies of the community and has some idea where to turn to find assistance in making suitable adjustments that will enable the patient to continue treatment or to protect others. The possession of such qualities enables the public health nurse to perform a superb service as a go-between for clinic and home, physician and patient, the patient and his family, his friends and his employer. Thus equipped, she is

* Read at a Joint Session of the American Social Hygiene Association and the Public Health Nursing Section of the American Public Health Association at the Sixty-third Annual Meeting in Pasadena, Calif., September 3, 1934.

far too valuable to devote her entire time to determining eligibility, or to routine clerical assistance of such proportions that no time is left available for the very important social and educational measures which should be a part of every clinic.

Within the clinic the nurse makes a contribution to case control by the manner in which she receives patients. The ability to put herself in the patient's place and treat him as she herself would wish to be treated under similar circumstances, is her most valuable asset. She is interested in the patient as a human being; not as case "No. 768." When she approaches the printed forms intelligently and not in the manner of saying "Just another case," she wins the confidence of the patient. One clinic reports that the giving of false addresses and delinquency in returning for treatment are rare. Another finds just the opposite to be true. Is this not due to the manner in which patients are treated? No individual relishes indifference or haughtiness. It matters greatly to the patient whether he is received by a disinterested registrar who routinely follows a list of questions, or whether he is met by a personality sensitive to his problems. The nurse who can, through carefully directed conversation, obtain all the pertinent facts without direct questioning and without antagonizing and arousing negative reactions, performs an effective part in case control.

Careful history taking is another important contribution which the nurse makes to case control. If the nurse's records contain such phrases as "history of contacts not significant," or if she permits herself to be so dull as not to find one hint of the source of the patient's disease, it is no wonder she is sometimes relegated to less important services such as "pulling" histories and making out appointment slips. Many clinics, however, have learned the

economy of correct history taking by a careful nurse. It is an indispensable aid in the discovery of possible cases, and in dealing with cases where special adaptations are indicated; for example, while taking history one day, the nurse observed that the patient fidgeted considerably and that her eyes turned repeatedly toward the clock. She immediately sensed the patient was in a hurry and in response to one sympathetic comment she learned that the woman had left a sick baby at home, that her husband was taking care of it but had to be at work at a given hour which fast approaching, and that the woman had already waited her turn for 2 hours. The nurse then handled the situation so that an exception was made to the usual routine and the woman was seen by the physician and enabled to return home and relieve her husband in time for his work. The nurse noted on record "family responsibilities," which would indicate to any of the clinic personnel that special adaptation was required.

Patients appreciate such individual treatment and when it is received there is seldom any call for coercion. Necessity for coercion should be considered reason for frank acknowledgment of failure on the part of clinic personnel. The patient has understood or has not been understood.

The usual function of the nurse, as interpreter to the patient the specialist's findings, renders her of utmost value in case control. Every patient will respond to a clear explanation of his particular case and with more enthusiastic coöperation. The nurse realizes that no two cases are ever exactly alike and recognizes the need, as interpreter, to connect the physician's findings with facts in the patient's own environment that his interests and attitudes may be sufficiently stirred to motivate coöperation.

Every person who has been success-

fully treated for syphilis should be urged to become a teacher in the campaign for prevention and cure of the disease. In some clinics a nurse regularly conducts a lecture to a waiting group. This appears to be a valuable method of case holding. Patients who think they are cured after a few injections, or after 1 negative Wassermann, or when they feel "perfectly well," ordinarily become delinquent. By clarifying and explaining why these are not good reasons for discontinuing treatment, the nurse holds many of these cases without lapses. The lecture period makes clearer to patients the urgency of reporting promptly anything which is troubling them in relation to treatment—a painful injection, an unexpected reaction, or any social circumstances which make clinic attendance difficult.

The nurse tries to excite an emotional reaction against the present state of affairs and a hope of something better. She presents a truthful picture of the tragic effects of untreated syphilis and tries to inspire each patient with a sense of responsibility, not only to himself, but to his family, and to the community who have to bear the suffering of congenital syphilis or the miserable effects of late lues. She also explains, in simple language, the ways in which syphilis is transmitted, the necessary concurrent disinfection, and the hygienic measures the patient should adopt to protect others, and urgently emphasizes the necessity of immediate observation and careful examination of all contacts.

The nurse often makes herself valuable as an educator in other ways within the clinic. She endeavors to guide all the patient's experiences within the clinic, so that they may favorably influence "his habits, his attitudes and knowledge" in relation to the prevention of syphilis. She tries to have the waiting and examining rooms arranged and managed in accordance with hygienic values. She tries to do

away with unnecessary massing of patients in one crowded waiting room for long hours of waiting. She takes an interest in the decoration of walls and the supply of pamphlets and pictures of an educational nature.

An elderly patient who had just been employed, after 2 years without any job, came to a clinic one day at noon, hoping to have an early chance for treatment. A large group was already waiting. The old gentleman waited until it was almost 2 o'clock and then when he explained to an attendant that his new job demanded that he be on duty at 3 o'clock. "Have to wait your turn," snapped the attendant, and a few weeks later the public health nurse had to hunt up another delinquent. As one discordant instrument in the orchestra ruins the symphony so one member of the clinic staff who is not in harmony with the ideals of individualization for case holding spoils the work already done by others.

Most clinics waste too much of the patient's time. Various adaptations of the appointment system have largely overcome the long periods of waiting. Still when carfare and absence from work require deprivations of a sort, clinic appointments should be carefully gauged. The nurse has an important part to play in emphasizing courtesy and individualization of the patient.

Well regulated clinics find some sort of efficient follow-up system indispensable, not only for case holding in a few instances, but for case finding among contacts of a syphilitic patient. Here again, the public health nurse functions. She visits homes and, with understanding and tact, makes an approach which leads patients, new and old, to the clinic doors. If the nurse serves periodically within the clinic in close coöperation with the physician she finds familiarity with present-day procedures a distinct advantage outside the clinic. It makes her more adept in

case finding and in handling the perplexities of patients, especially in relation to misunderstood instructions. She helps to make social adjustments. Frequently she is called upon to clarify a patient's position in relation to his employer, and thus wins the patient's gratitude and renewed will to cooperate by helping him to hold a job from which an employer, untutored in the communicability of the disease, had unwisely expected to "fire" him.

The public health nurse, in the field, seeks to stimulate interest in routine Wassermanns on all prenatal cases; supervises the new-born babes of syphilitic women. She realizes that public information regarding syphilis is woefully lacking and tries to develop a sane, unemotional attitude toward it. Some years ago families tried to hide tuberculosis if it existed in their midst and thereby failed to take proper measures for its control in fear of an imagined stigma. What marvelous progress in change of attitude was indicated when several years ago, the newspapers of the country broadcast that a son of the President of the United States was found to be a victim of early tuberculosis and was to receive prompt treatment in a mountain rest home! Such publicity might never be desirable in relation to syphilis, but surely it is obvious that a change of attitude in regard to it must continue.

It has been estimated that about 10 per cent of syphilitics contract their infection in an innocent way. It is well also to recall the words of Dr. John Stokes, who writes that "no genealogic tree is so pure that syphilis has not twined itself among its branches." The nurse who carries into the homes a calm, scientific attitude toward this disease helps to bring about the revelation of many new cases.

Every case found, carefully studied for the identification of his intimate contacts, is a means of prevention and

eradication of the disease. The follow-up depends for its success upon a very thoughtful method of approach. In this connection Dr. Nels A. Nelson writes as follows:

The search for "sources of infection" requires understanding. It is unfortunate that the term "source of infection" ever came into use in this connection. It is the most antagonistic approach that could possibly be made. A person who is accused of having infected another is quite naturally on the defensive. It is a perfectly understandable reaction. It is often an unjust accusation. The patient, on being questioned as to his exposures, naturally thinks of the last one. The incubation period is long enough and variable enough so that his contacts during that period may have been many. The last partner may have been exposed to his infection rather than have been the cause of it. Or the patient may have an acute recurrence of an old neglected infection which he mistakes for a new one. All of his recent contacts may then be victims of the patient's infection.

It is always safest to approach a contact, whether or not the alleged source of an infection, as the possible victim of an infection. Certainly every "source of infection" must, at some time previously, have been the victim of another infection. The person thus approached is concerned in his or her own interest as the offended party. As there is no need for defense against accusation, the advice to seek medical attention is more readily accepted. It is better to think always in terms of case-finding than in the uncertain and often unjust term of search for the "source of infection."

CONCLUSION

In spite of the large number of syphilis clinics in the United States there are very few localities where a well rounded piece of work is being carried on. There is need, in general, for less secrecy and a more scientific attitude toward this very prevalent disease, and in particular there should be greater individualization of cases. Each case is a potential teacher, each case a pivotal point for the location and eradication of many other cases.

Success of the most efficient medical treatment rests upon a well rounded

supporting service, in which every member of the staff shall be imbued with the ideal of complete eradication of syphilis, that the ever present danger in any institution of letting it degenerate into a machine shall be obviated. The Master

has told us that "not a sparrow falleth" without the Creator's attention. When such is the spirit of the clinic its service to humanity in the eradication of human misery due to disease will have manifoldly increased.

Campaign Against Diabetes

ORGANIZED work against diabetes in New York City has begun with the formation of the New York Diabetes Association, affiliated with the New York Tuberculosis and Health Association, and to be associated with it at its headquarters, 386 Fourth Avenue, New York, it has been announced.

The formation of the service on diabetes was made possible through a special contribution of \$15,000, given by Lucius N. Littauer, toward the first three years' work.

In presenting his subscription, Mr. Littauer expressed the hope that the establishment of this work against diabetes would lead to the control and possibly the reduction of the growing mortality from the disease, and stressed the fact that the coördination of activities in the fields of both tuberculosis and diabetes would result in mutual benefit to sufferers from these diseases, as diabetes greatly aggravates the condition of tuberculous patients.

Commenting upon the formation of the new association, Dr. Charles F. Bolduan, of the Department of Health of the City of New York, pointed out that the registered deaths from diabetes in New York City have increased since 1923, when there were only 1,360, to

2,141 during 1933—a figure which puts the disease here among the leading causes of death. Twice as many women as men die of diabetes, he added; last year there were 1,418 of the former and 723 of the latter.

The New York Diabetes Association proposes to act as a clearing house for the study of the disease as a health problem and to devise measures for its control; to assist in the formation of an association of clinics dealing with diabetes; to develop graduate courses of instruction for physicians; particularly to carry on health education of the general public in all matters pertaining to the disease; and to obtain the provision of insulin for indigent diabetics, and nursing service and hospitalization for all requiring it.

The association plans to operate in a city-wide basis under the leadership of noted physicians in the diabetic and metabolic fields, and to include in its council representatives of the tuberculosis and health associations, members of the New York Academy of Medicine, of the Departments of Health and Hospitals of the City of New York, of the county medical societies, of schools of medicine; public and private hospital authorities; representatives of social and welfare agencies, and interested laymen.

Nutrition and Health and the Price of Milk*

JAMES A. TOBEY, DR.P.H., F.A.P.H.A.

*Director of Health Service, The Borden Company,
New York, N. Y.*

DAIRYING has long been recognized in this country as a basic industry, the proper conduct of which is essential to our national progress, welfare, and prosperity. Milk is, in fact, the most important agricultural commodity in the United States. This prominence is due not merely to the fact that milk and milk products from American farms constitute our greatest single source of agricultural income, but because the regular consumption, by all of the people, of more liberal amounts of pure milk and dairy products unquestionably would be an important factor in the improvement of national vitality.

This desirable increase in the consumption of clean and safe milk and its many products is, therefore, a matter of both economic and biologic significance. Biology and economics are factors that are closely interwoven in the whole science and art of public health, particularly in matters relating to human nutrition. If we could solve the intricate problems of supply and demand, of costs and prices, of reasonable regulation, and of better public appreciation of dairy products, we should contribute immeasurably to

human welfare, both with respect to national prosperity and public health.

MILK CONSUMPTION AND THE PUBLIC HEALTH

Despite the fact that modern science has demonstrated in a long series of brilliant investigations that milk is indispensable to adequate human nutrition, and that the dietary qualities of dairy products surpass those of practically all other foods, the average American consumes too little milk. In 1933, the annual per capita consumption of fluid milk and cream was only 38.8 gallons, or 0.85 pint, a day. Sectionally, some parts of the United States are much worse off in this respect than are others. In the South Atlantic and South Central states, the daily average is only about $\frac{2}{3}$ pint a day, whereas in the North Atlantic states, nearly 1 pint of milk was taken by each person every day. In the Western and North Central states the daily quantity of milk consumed was about the same as the average for the whole country.

Our per capita milk consumption is now about where it was a decade ago. Up to 1929 it was steadily rising, the annual increase being due in all probability to improvement in the sanitary quality of market milk supplies, greater public confidence in the safety of milk, more extensive knowledge of its nutritional benefits, and greater purchasing

* Read at a Joint Session of the California Association of Dairy and Milk Inspectors, the California Dairy Industries Association, the California Dairy Council, and the Food and Nutrition Section of the American Public Health Association at the Sixty-third Annual Meeting in Pasadena, Calif., September 4, 1934.

power in those relatively prosperous times. Since 1929 there has been a consistent decrease from a per capita of 40.8 gallons in 1929 to 38.8 gallons, or a reduction of about 5 per cent. Until the coming of the drought, there had not been an accompanying decrease in production, which is one of the several reasons why we have a milk problem.

Scientists who have worked out the mass food requirements of the American people on a careful nutritional basis declare that even in a restricted diet for emergency use, 155 quarts, or 38.75 gallons, of milk are necessary for each person in the course of a year. Today our people are, therefore, barely living on a restricted and meager milk diet. For an adequate diet at minimum cost, not less than 260 quarts, or 65 gallons, of milk or its equivalent in other dairy products is advised. For an adequate diet at moderate cost, or for a liberal diet, the per capita figure is set at 305 quarts, or 76.25 gallons of milk annually.¹

From these authoritative data, it is obvious that milk production and consumption in the United States ought to be increased by about 70 per cent. In theory, an increase in milk production, from the present 3,269,470,000 gallons annually to more than 6,000,000,000 gallons, is economically and biologically sound. The difficulty is an impassive public, not yet wholly convinced that pure milk is what it is, an economical and inexpensive food of unique dietetic properties.

MASS STUDIES ON THE VALUE OF MILK CONSUMPTION

The people of the United States, living under an aura of scientific progress, are, strangely enough, much less addicted to the use of dairy products than are the citizens of many other nations. Our per capita consumption of whole milk has always been exceeded by that in Finland, Switzerland, Norway, Can-

ada, and the Netherlands.² The consumption of butter is far greater in New Zealand, Canada, Australia, and the Netherlands than in our country, where butter is so abundant. In the use of cheese, we rank 12th, our consumption of this nutritious and savory product being less than half that of the peoples of 9 other nations. It may be more than a mere coincidence that the general death rates are lowest, the duration of life is longest, and the people are most rugged, in countries where the consumption of sanitary dairy products is greatest.

The favorable influence on healthful longevity of the regular consumption of optimum amounts of pure milk is now as well established as is the unfavorable effect on infant and general mortality of impure and contaminated raw milk. Proof has come from the laboratory that milk consumption is conducive to life prolongation.³ If, however, statistical data for entire nations have not yet been adduced to confirm this fact, other interesting scientific experiments have demonstrated the value of increasing the use of milk in large populations. Two of these studies are worthy of special mention.

The most noteworthy and most extensive investigation on milk was conducted in Scotland.⁴ Between 1927 and 1930, nearly 25,000 school children participated in 3 separate tests to determine whether supplementary daily feedings of raw or pasteurized milk would influence physical growth. In the first test, involving 1,282 children over a period of 7 months, the milk-fed group showed an increase of weight and height 20 per cent in excess of those who were not favored with this extra milk. In the second test, which included 1,157 children, the milk groups increased their heights 23.5 per cent more than the controls, and gained 45.4 per cent more in weight.

For the third test, no less than 20,000

children were selected in the schools of Lanarkshire. In the course of 4 months, one-half of these Scotch children were given $\frac{3}{4}$ pint of tuberculin tested milk every day. Raw milk was given to 5,000, and pasteurized milk to 5,000. The results confirmed the previous experiments, showing conclusively that milk makes a notable difference in the physical development of young children. During the comparatively short period of this test, the milk-fed group gained on the average from 4 to 6 ounces more in weight than the controls. Another feature worth noting was that there were no measurable differences in the effects of raw and pasteurized milk. Recently a careful statistical analysis of the data, made by dividing the children into identical pairs, was carried out in the laboratory of Professor Karl Pearson.⁵ The observation that children who have extra milk gain in height and weight over those who do not was confirmed, as was also the fact that pasteurized milk is as efficacious as raw milk for this commendable purpose.

A law passed in 1930 in Scotland empowers local authorities to supply graded milk to school children, a policy deserving of emulation in our own country. "It is expected," says an editorial in the London *Lancet*,⁶ "that this power will be widely used in the near future and will result in a noticeable improvement in the physique of the Scottish race."

The definite influence of milk consumption on the physique and general health of a race has been shown by another recent study, conducted by British medical officers in Africa.⁷ Examination of the members of two neighboring tribes in Kenya revealed that the full-grown male of one tribe, the Masai, was on the average 5 inches taller, 23 pounds heavier, and had 50 per cent greater muscular strength than the adult male of the other tribe,

euphoniously known as the Akikuyu. Marked difference was also found in the incidence of disease in the two tribes, bony deformities, dental caries, anemia, pulmonary maladies, and tropical ulcer being more prevalent among the physically smaller Akikuyu.

When the physicians sought for a reason for these differences, they discovered that the diet of the stalwart Masai consisted mainly of milk, meat, and raw blood, whereas the sustenance of the puny Akikuyu was derived from cereals, roots, and fruits. In other words, a milk and meat diet makes strong men with powerful physiques, and a strictly vegetarian fare produces weaklings. This fact has been noted before in the course of human history, for the conquerors have always been owners and users of cows, and not eaters of grasses and grains. The victors have been victorious on diets of calcium and protein, and not on carbohydrates.

FACTORS INFLUENCING MILK CONSUMPTION

Granted that these two examples, selected from the many scientific investigations on milk that could be cited,⁸ offer persuasive and cogent reasons for augmenting the national consumption of pure milk, the question arises as to what factors must be considered in attempting to bring about an increase of the use of milk in the United States. Certainly, the milk companies and the various national organizations supported by them have been endeavoring to perform this praiseworthy task, and in doing so, have always had the active coöperation of federal, state, and local health and agricultural officials.

The primary factors affecting milk consumption are: (1) the availability of milk, (2) the quality of milk, (3) the cost of milk, (4) the wisdom and knowledge of the public, and (5) the purchasing power of the consumer.

Milk of good quality is now generally available in all parts of this country, although the quality is, on the whole, much better in the larger cities than in the rural sections. This improvement has been due in part to a gratifying increase in the amount of pasteurized milk—some 88 per cent of all our market milk now being pasteurized, if the possibly rather optimistic estimate of the U. S. Public Health Service is correct. In the few regions where fluid milk is unobtainable, or in those places where its purity may still be questionable, the public can always obtain the concentrated milks, including evaporated, powdered, and condensed. These processed milks exhibit virtually the same nutritional properties as pasteurized milk, and they are clean, safe, and in some instances, sterile.

The knowledge of the public regarding milk is one of the outstanding factors affecting its consumption. Better education of the people as to the merits of milk tends to bring about gratifying retention of milk and dairy products in the diet, even in times of depression, a phenomenon which was emphasized by Dr. A. Gorini of the International Labour Office in an address at the recent World's Dairy Congress in Rome (April 30–May 6, 1934). He called attention to studies in Belgium and Germany which revealed that increases in the purchasing power of the worker invariably resulted in greater uses of milk and dairy products, with corresponding decrease in the use of the less nutritious cereals and potatoes. This observation is not novel, but is the basis of one of the dogmas of economics.

Education can, however, often alter erroneous sociological principles, a fact which is beginning to percolate even into the consciousness of the sovereign power. The Legislature of the State of New York recently appropriated half a million dollars to advertise the estimable qualities of milk as food. This cam-

paign, which is now in progress, is financed by levying a tax of 1 cent per 100 pounds of milk and cream sold in fluid form, half of the amount to come from producers and half from distributors. As usual, the industry pays, and it would seem more logical if this worthwhile campaign were conducted by the industry itself, rather than by the state, which should, nevertheless, lend the weight of its authority to the support of it. Milk is not a public utility, according to a recent decision of the United States Supreme Court,⁹ although the milk industry is subject to reasonable regulation in the public interest.

Milk is not a public utility, nor is it a luxury. If all the people could be made acutely cognizant of the economy and the necessity of milk consumption, and aware of the fact that money devoted to the purchase of milk produces a substantial return on the investment, there would be much less agitation and misconception regarding the alleged high cost of milk.

FACTORS AFFECTING THE PRICE OF MILK

As with every industrial commodity, the price of milk is governed to a considerable degree by supply and demand. Theoretically, the present supply of milk in this country is only a little more than half what it should be in order to meet the health requirements of the nation, but actually the demand is less than the supply.

One of the causes of this unhealthy state of affairs has been a great expansion of the dairy industry in recent years, an expansion which ran full tilt into the economic depression. Between 1929 and 1933 there was an increase of 14 per cent in the number of dairy cattle in this country, or a rise from some 21,000,000 cows to about 26,000,000. Experience has shown that increases in the cow population occur in cycles of about 15 years each, 7

up and 7 or 8 down, and that we are now at the peak of one of these cycles. Aside from this bovine cycle, however, there has also been a steady increase in the number of dairy cattle, due to human population increases and other biological factors.

Although the demand for milk has not kept pace with the supply since 1929, the decrease in milk consumption has been less marked than in the case of many other products affected by the depression, even, in some instances, where prices were drastically reduced. This provocative fact may afford us some comfort.

The price of milk declined with the depression, but not to the same extent as some other dairy products, such as butter and evaporated milk. If the decline in the price of fluid milk had been too drastic, the depression might have been accentuated, because the leading cost factor in the milk industry is labor. The maintenance of the wage scale is obviously a matter of great economic and sociologic significance.

Two-thirds of the retail price paid for a bottle of milk is devoted to the compensation of labor, including that of the farmer, although the expenses of the farmer also include feed and other supplies. In New York City, for example, the average retail price paid by the customers of the largest milk company in 1933 for all grades of milk was 9.1 cents a quart. Of this, 4 cents went to the farmer or his agent, the coöperative, and $2\frac{3}{8}$ cents was paid for labor, including the personnel at country milk plants, at pasteurizing and bottling plants, in laboratories and offices, the delivery and sales staff, and the veterinarians and inspectors. Adequate sanitary supervision adds, of course, to the cost of milk, but is worth it.

Of the remaining one-third of this average retail price, $1\frac{5}{9}$ cents was spent on materials, such as bottles,

cases, and cans, on coal and gasoline, on feed and bedding for horses, and their replacement, on the maintenance and wear and tear of vehicles, and of dairy plants and their equipment. Another $\frac{7}{8}$ cent went for railroad and motor transportation. Advertising received only $\frac{1}{16}$ cent, taxes $\frac{1}{9}$ cent, and officers' salaries only $\frac{1}{50}$ cent. Although the big milk companies have been accused of paying enormous salaries to their executives, the largest companies actually have lower costs for this purpose per quart of milk than the small companies.

After all these necessary expenses have been met, the little that remains is profit. In the case outlined, this amounted to about $\frac{1}{8}$ cent on each quart of milk sold, which went to thousands of individual stockholders, who put this money back into circulation. Studies of the profits of 19 milk dealers in New York City, including the 5 largest companies, reveal that in August, 1933, they had to sell 143 quarts of milk in order to make 1 cent profit.¹⁰ In 1934, under the exacting requirements of the N.R.A., the A.A.A., and the rest of the federal alphabetical gamut, many of the milk companies were operating at a loss. No one but a moron or an agitator could claim that profits such as these are excessive, although there are plenty of persons in both of these categories, some of them in high places, who do say so.

THE ECONOMY OF MILK AS A FOOD

Despite the fact that the most sapient authorities on nutrition, including government officials, professors, and other pundits, universally advocate the expenditure of from one-fifth to one-third of the family food budget on milk, the actual expenditure for this indispensable food is now only about one-tenth of the average American food budget. The fraction now allotted to milk could be doubled without increasing the daily

expenditure for food. Departure from a false and penurious policy regarding the purchase of milk would, moreover, more than double the nutritional value of the diet, and would also react favorably upon our dejected dairy industry.

The true economy of milk can be demonstrated by comparing the costs of its nutritional constituents, its fat and carbohydrate, its proteins and minerals, and its vitamins, with other staple foods. The comparison will be found favorable to milk, the average retail price of which in this country is now about 11 cents a quart, or approximately 5 cents a pound, or $1\frac{2}{3}$ cents per 100 calories provided for the proper functioning of the human machine.

Pound for pound, milk is cheaper than all other foods, except one or two of the vegetables, but this basis of comparison is not, of course, strictly fair. In 100 calory portions milk is less expensive than many foods, and it is, therefore, a relatively inexpensive source of energy. Most meats, for example, exceed 3 cents per 100 calories, in contrast to milk at $1\frac{2}{3}$ cents. Fruits and many vegetables bought in cities will cost from 3 to 20 cents per 100 calories. Breads, cereals, potatoes, and a few other vegetables are cheaper than milk as sources of energy, but fuel is about all that some of these foods provide, whereas milk gives much more than that. Calories are only a part of the story.

As a source of protein, milk is cheap, and cheese is even cheaper. The cost of 100 protein calories from cheese is, in fact, less than half the cost of the same number in beef, and only a third that of eggs. If we could put a price on calcium and phosphorus, the minerals requisite for strong bones and teeth, we would find that milk is exceptionally cheap. It is the best dietary source of these necessary minerals and it yields the daily gram for a price far below any other food. An equivalent

amount of calcium from lean beef, for example, would cost the consumer 100 times as much as from milk. Securing calcium from spinach costs $3\frac{1}{2}$ times as much as from milk.

The vitamins in milk are worth money. Since, however, it is difficult to assign financial values to them, the vitamins may be considered, as Rose has suggested,¹¹ as profits on the investment in milk. Consumers pay fancy prices for cod liver oil, which contains vitamins A and D, and yet whole milk provides an adequate supply of vitamin A, and 1 quart of irradiated milk not only furnishes as much vitamin D as 3 teaspoonfuls of cod liver oil, but is more effective as an antirachitic, according to authoritative clinical studies.

All factors considered, milk at its present price, or at double that price, is an economical food, worth not 11 cents but nutritionally at least 18 cents a quart. The daily quart needed by every growing child, every expectant and nursing mother, and every undernourished person, and the daily pint for every other adult, is health insurance at a very reasonable cost. The quickest way that the cost of distribution of milk could be appreciably lowered is by a material increase in the national demand for our most nearly perfect food. Such an increase should be the goal of every progressive health official, who, while alert to safeguard the cleanliness and safety of the milk supply of his community, owes an equal duty to the public health to promote the greater consumption of pure, pasteurized milk and of the other salubrious dairy products. The solution of the dairy industry's present plight is not a decrease in production, but an increase in consumption.

SUMMARY

Although milk is recognized as our most important food, the consumption in this country is now far below the

acknowledged standards of an adequate diet at a reasonable cost for all the people. The consumption of milk in the United States should be increased at least 70 per cent.

Mass studies on milk consumption in various parts of the world have demonstrated the beneficial effects of higher milk consumption upon physical welfare.

The consumption of milk is influenced by such factors as the availability of clean and safe milk, the cost of milk, the purchasing power of the people, and the education and understanding of the public as to the unique value of milk in human nutrition.

The price of milk is affected by such factors as supply and demand, the demand not having kept pace with the supply in recent years, and the costs of human labor, which has been maintained at a high level during the depression.

The spread between the price paid to the farmer and that paid by the consumer is due to necessary costs and is not represented by profits to the distributor. The actual profit on each quart of milk sold generally does not exceed a very small fraction of a cent.

At its present price, or at double that price, milk is or would be an economical

food, giving a better return on the nutritional investment than any other food, or many combinations of foods.

The solution of the economic problem of the dairy industry is not through a decrease in production, but by an increase in consumption of milk and dairy products, an endeavor which deserves the active coöperation and assistance of all public health officials.

DISCUSSION

J. C. GEIGER, M.D., F.A.P.H.A.

Director of Public Health, San Francisco, Calif.

IN this discussion perhaps it would be best as a health officer that the discussion be confined to the aspects of wholesomeness and safety of milk.

Milk as a food and beverage was generally used among the ancients. Certainly, butter was used in India as early as 2000 B.C. Milk has a unique position in our dietary in that it is more universally used than any other

food commodity. As such, it has a most profound influence on the health of the people. It contains all the food elements, namely, fats, protein, carbohydrates, mineral salts, and vitamins. Therefore, as a so-called well balanced ration it stands supreme. If one desires to state it popularly, it has sugars and fat to warm you and to make you plump but not over-plump, protein to

give you strength, mineral to build your bones, and vitamins to stimulate growth.

In the United States, the production of milk has increased enormously. Likewise, the sanitary measures to protect its safety as a food have increased. The price to the ultimate consumer, however, for many economic reasons, has remained stable. It may be stated without fear of contradiction that making milk a political holiday has become unpopular and today we have the intelligent coöperation of the modern health officer, the producer, and the distributor.

There could be considered adverse and scientific periods in the production and sale of milk. Among these so-called periods was that of dilution with water, preservation with chemicals, tuberculosis, certification, pasteurization, and last but not least, abortion and Malta fever. Perhaps the most important periods are certification and pasteurization. The problem of tuberculosis apparently is being met, but the problem of abortion and Malta fever is at present obscured in a mass of detail that needs intelligent unraveling in order that practical preventive measures can be adopted.

One of the really important services to be rendered in conserving public health of any community is the provision of a safe milk supply. Such a supply will earn its dividend in a general low death rate, but particularly to be noted, in the death rate under 2 years. Moreover, a safe milk supply is a community advertisement to be stressed. Milk taken from healthy cows under sanitary conditions is usually comparatively free of germs. Unfortunately milk so produced is too often the exception rather than the rule. Therefore, dairy sanitation should begin at the source, the dairy farm.

Contamination with germs ordinarily begins with the act of milking and the

route to the consumer is fraught with possibilities of contamination which are many and varied and often dangerous. Consequently, proper pasteurization is a necessary requirement for the general milk supply. Pasteurization properly done never was intended to atone for lax sanitary methods. Neither should it give the dairyman a false sense of security in not maintaining a healthy dairy herd. As policy, all milk should come from healthy cattle. Again, each distributing district or area or city should maintain routine inspection of the dairy farms along with the inspection in the district receiving and pasteurizing stations and at the city railroad platforms in direct shipments. These examinations would consist of sediment, chemical and temperature tests, as well as those for color, odor, taste, and of the containers.

The health officer is actively concerned with safeguarding the supply against such infections as tuberculosis, typhoid fever, diphtheria, scarlet fever and septic sore throat. Pasteurization is greatly depended upon to do this. Another factor of safety can be added by not permitting milk to be distributed from farms where there exists a contagious disease, and the same rule applies to employees of pasteurizing plants. In fact, it is considered good practice to submit such employees to routine physical and laboratory examinations and to immunize them against certain communicable diseases.

The production of certified milk practically dates back some 30 years and should be the only raw milk permitted to be distributed. Tuberculin and possibly abortion tests of the herd and of any additions should be required semi-annually. The health officer should have such test records on file. Monthly physical examinations should be made of the dairy attendants along with such laboratory examinations as are considered necessary with immunization

against certain communicable diseases.

Pasteurization should be required for all milk, except that which is certified, sold in any city. There is no doubt that the merits of this process in safeguarding public health against milk-borne infection are thoroughly recognized. Pasteurization consists of heating milk to a temperature of not less than 145° F. and keeping it at that temperature for not less than 30 minutes. We cannot too strongly emphasize, however, that this process is not a substitute for sanitation or as a corrective for milk from diseased cattle. It must also be recognized that the control of proper pasteurization is to a great extent dependent upon the human element. The possibility of some mechanical defect is manifest and careful survey and continuous inspection of pasteurization plants are essential.

The Director of Public Health of San Francisco wishes to record the fact that he disapproves the present tendency of manufacturers to add measured quantities of vitamins to foods for commercial purposes. The insufficient and

incomplete scientific knowledge available at this time on the possible effects of the consumption of vitamin reinforced food products over indefinite periods fully justifies the attitude that caution should be observed in the use of such products. There is still considerable question, particularly concerning vitamin D, of what constitutes the proper dosage of vitamin concentrates in the various age groups. Any attempt to increase the sale of a food product, especially milk, by the addition of a substance whose value to the public health is still a controversial matter is indeed ill advised, since the final evidence, to be determined by research, has not yet been secured. Even if it is granted that the actual danger in the consumption of vitamin D milk is relatively minimal, there is as yet no definite and accepted information on the limits or margins of clinical safety. Under these circumstances it is believed that the administration of such products should be surely in the province of the physician and not in that of the commercial distributor or manufacturer of food products.

Medical Care in the United States

HOW are we situated in regard to the so-called services? About every fifth bed in hospitals (except those for mental cases) is vacant, while at the same time only half the people who need hospitalization can either get it in "charity" wards or buy it. A large percentage of our doctors and nurses are idle, while sick men everywhere are dying without receiving medical attention.

As a nation we spend \$3,250,000,000 for health, or \$26 per capita, whereas we should be spending \$42. In consequence, the death rate is in inverse proportion to income—the unskilled, poorly paid workers die at the rate of 1,440 per 100,000, while the skilled workers die at a lower rate of 829 per 100,000; managers and officials at 793, and professional people at the rate of 670.—*The New Republic*, Dec. 12, 1934.

PLAN

Pipettes for Use in Routine Sterility Tests

W. E. BUNNEY, PH.D.

*Associate Director, Bureau of Laboratories,
Michigan Department of Health, Lansing, Mich.*

THE pipettes described in this note are designed to facilitate the routine sterility testing of biologic products done in accordance with the regulations of the National Institute of Health. The pipettes have been in use for over a year, and have proved valuable not only in speeding up the actual testing, but in saving both time and material in the washing and sterilizing of glassware. They have an additional advantage in that the inoculation of fermentation tubes with the material to be tested is uniformly accurate.

The National Institute of Health regulations require that products whose human dose is 1 c.c. or less should be tested by the addition of 5 drops to one, and 20 drops to another of two fermentation tubes from each container tested. This requires a pipette graduated at 1 c.c. and 1.25 c.c. The regulations require further that products whose human dose is more than 1 c.c. be tested by the addition of 20 drops to each of successive fermentation tubes until the full human dose has been inoculated. If the human dose is 5 c.c. or more, only five fermentation tubes are inoculated with 20 drops each from every container tested. To meet these requirements, the pipettes described below and shown in Plate I were devised.

It was decided that a satisfactory pipette would have to meet the following requirements:

1. It should be free flowing. Too slow a delivery needlessly slows up the testing procedure. A minimum inside diameter of 1 m.m. was specified since the flow through a 1 mm. lumen was found to be satisfactory.
2. The pipette must be easy to insert through the neck of any final container to be tested and it must be possible to insert it far enough to reach the bottom of the container. For this reason a maximum outside diameter of 4.8 mm. for a distance of 75 mm. from the delivery tip was specified.
3. The pipette must not be awkward to handle. A maximum over-all length of 350 mm. was specified since a longer pipette was found to be unwieldy.
4. The pipette must be easy to read. In order to facilitate reading, all graduations were made in a complete circle about the pipette. A distance of 100 mm. from the plugged end of the pipette to the top graduation was specified so that the pipette could be held comfortably without the fingers obscuring the graduation.
5. The pipette should be easy to plug and there should be no danger of the plug sucking down into the liquid under test. An inside diameter of 6 mm. was specified for the mouth piece and a constriction to an

inside diameter of 1.5 mm. made at least 5 mm. from the mouth piece end. This gives room for a good sized plug and obviates any danger of its slipping down into the pipette.

6. The pipette should be made of resistant glass in order to reduce breakage.

The complete specifications are as follows:

- 5 c.c. pipette—graduated in c.c. to tip—length from delivery end of bulb—75 mm.
- Length from bulb to tip—75 mm.
- Overall length approx.—350 mm.
- O.D. (except bulb)—4.8 mm.
- Lumen, mouth piece—6 mm.

Lumen, del. end, not under 1 mm.

Constriction—1.5 mm. I.D. above bulb

Graduations—in 1 c.c. to tip, complete circles

- 1.25 c.c. pipette—Distance from plugged end of pipette to beginning of graduation—100 mm.

Constriction—5 mm. from plugged end to about 1.5 mm.

O.D.—4.8 mm. maximum

Diameter of lumen, del. end—not under 1 mm.

Graduations—at 1.25 c.c. and 1.0 c.c. points only—complete circles

Resistance glass

Emergency Nursery Schools

APPROXIMATELY 50,000 children are enrolled in the 1,600 emergency nursery schools which exist under the F.E.R.A. in 47 states, the District of Columbia, and Puerto Rico, according to Grace Langdon, Ph.D., Specialist, Emergency Nursery Schools. Through these nursery schools young children and their parents have derived many benefits since the time of their authorization in October, 1933. Children have found physical comfort and relief from the strain occasioned by overcrowded living conditions and worried adults. They have, day by day, learned those health habits fundamental to wholesome living. They have had the opportunity to play with others of their own age, and to learn the social habits that come from such play. Parents have learned how to provide better physical care for their children and how to guide

their behavior better. Many communities which heretofore knew little about nursery schools have seen the above mentioned services and are already laying plans for making nursery schools a permanent institution in the community, since they have demonstrated in some measure their function as a social agency.

In laying such plans care needs to be taken that only the best of the emergency program is preserved, and that in building for the future there is ever kept in mind the standard of what a good nursery school really is and that only the best is planned for any community. This points to the need of informing one's self concerning the standards for a good nursery school and passing on that information to the general public.—*Parent-Teacher News Release*. Jan. 25, 1935.

VITAMIN D MILK

THERE is always something new coming up concerning milk. For a number of years it was chiefly the discussion of bovine tuberculosis and its transmissibility to human beings. The English and our Canadian friends are still struggling with this question which has come to the fore on account of investigations made within the last few years in those countries. In America the matter was threshed out some 30 years ago. To our Bureau of Animal Industry we owe our present excellent position in regard to this question. Pasteurization is now so general in our cities, at least, that cases of bovine tuberculosis in human beings are not common.

Next came the vitamins, and later the evidence that some, instead of being a single substance, carried several of these remarkable products. For the past 2 or 3 years the discussion has centered largely around the so-called vitamin D milks, and they are being urged on the public from a number of different directions, many of them entirely commercial.

Let it be said at once that there is no question about the fundamental facts involved, or the real value of vitamin D milk, properly prepared. The methods of making vitamin D milks and a discussion of them were published in this *Journal* in the issue of December, 1932, and since, editorials on the subject have appeared. There are three methods now in use for preparing vitamin D milk for the market: one by feeding cows irradiated yeast; one by irradiating the milk directly; and one by adding to milk a concentrate, usually made from cod liver oil (Zucker method). There is a fourth method—irradiating the cows—which need not be discussed here.

Each state and practically each city has laws regarding milk, with definitions of adulteration, pasteurization, modification, etc. A legal opinion has been rendered in one city allowing the sale of irradiated milk, but not vitamin D milk made

by the Zucker method, since it is forbidden to add substances to milk, but there is no prohibition against the use of radiant energy or the possible effects it may produce!

A recent report¹ discusses this question in what seems to us an eminently sane way, pointing out that the only milk which can be called "vitamin D milk" correctly is that produced by feeding cows irradiated yeast. Milk which is irradiated after being drawn should be called "irradiated milk." If the exposure is incorrect, there are substances in the milk which may be injuriously affected, and off-flavors developed, due probably to oxidization of fats or changes in the protein. It has been shown that there is some effect other than the change of provitamin substance into vitamin D, since skim milk can be activated. Indeed, skim milk, whey, and casein all contain sterol, but the lactalbumin has been found to contain a concentration which is more than half that of the butter fat, and that sterol so combined is more constant than that of the other milk constituents. The conclusion is that the sterol of the whole milk seems to be independent of the fat content.² Inquiries from a number of those supplying equipment and processes indicate there is no standard method applicable to the various types of equipment and apparatus. Recording ammeters in common use give amperage, but not ultra-violet radiation, though meters which record ultra-violet rays have been developed and others are being developed, but their practicability remains to be proved.

It will be remembered that Steenbock took out a patent on his irradiation method and turned it over to the Wisconsin Alumni Research Foundation, which has licensed a number of producers of evaporated milk. So far, clinical and experimental research on irradiated evaporated milk seems to be deficient. The foundation says that clinical studies have been conducted, but the results had not been published (July, 1934). The advertisements of various concerns manufacturing evaporated milk under license differ considerably. One states that the product is not offered as a cure for rickets, but as a reliable preventive of rickets for normal children. It seems impossible to reach any other conclusion than that the subject is still under study, and that much remains to be learned.

As far as the production of so-called vitamin D milk according to the Zucker process is concerned, the committee holds that the name is not correct, and that it comes distinctly under the head of "modified milks." The manufacturing of this product has been turned over to a company which is now putting the concentrate into cream, the object being to avoid the addition of an extraneous fat to the milk. Even this, however, will not overcome the legal objection to selling such milks under many of our existing laws.

Among the various bodies appointed to study this question generally is the Committee of the New York Academy of Medicine. After quoting an experiment to show that rats may be fed excessive quantities of vitamin D without injury, they say, "The advisability, therefore, of universal or general energizing of milk does not seem apparent." It is this point which we wish to stress, whatever form of fortifying is adopted. Reed³ has fed viosterol to 300 human subjects from 7 to 72 years of age, the doses ranging from 3,000 to 2,760,000 international units daily. Of these, 43 patients showed definite symptoms of toxic poisoning in varying degrees. He says that there need be little apprehension of poisoning through giving amounts ranging up to 150,000 international units daily for indefinite periods.

It requires pretty constant reading to keep up with the work which is being

done on the vitamins in general, and particularly vitamin D, during the last few years. As far as we can judge, those most competent to speak believe that there is much to be learned. If this is not true, many people are wasting money in useless experiments and study. However, the commercial interests have, as usual, taken hold of this idea and are pushing it. Even the Wisconsin Alumni Research Foundation is pushing it by methods which do not appeal to us. Their literature is apparently written by an advertising agent and abounds in short quotations which do not tell the whole story, though most are from those entitled to speak with authority. For example, one writer is quoted as saying, "The literature of the decay of teeth, osteomalacia, etc., gives definite evidence that vitamin D is necessary throughout the whole of life." This does not mean that any form of so-called vitamin D milk is necessary, though that is the implication, since there are many other sources of vitamin D available. The leaflet containing this statement is addressed to the medical and dental professions, but has been sent to a number of laymen.

In one pamphlet sent out late in 1934, statements are made which would indicate that this Foundation is working with the American Medical Association. It is true that the Committee on Foods of the A.M.A. has accepted a number of vitamin products, but they have also recognized the absence of clinical study and have set up tentative standards.

We do not wish in any way to be understood as objecting to the use of vitamin D milk. It does seem, however, perfectly clear that claims are being made for which there is no good evidence, despite which many so-called vitamin D products are being exploited by the milk industry and by patent and process licensors, and are being urged through the use of professional organization endorsement. We agree with the conclusion of the report from the A.P.H.A.—"Not until proper judgment and control of this entire matter is exercised by those having commercial, professional, and patent interests can it be expected that general confidence can be secured and the public given proper products scientifically proved to be of real merit or worth. Only by such method can exploitation of questionable products be prevented and legitimate products be accepted."

DR. THEOBALD SMITH—SCIENTIFIC PHILANTHROPIST 1859-1934

ON December 11, 1934, Dr. Theobald Smith, world-famous pathologist, died of heart disease at the ripe age of 75. His passing does not end his service to mankind, however, for the influence of his work will be immortal. He was a scientific philanthropist in the sense that his gifts in the form of new medical knowledge have added to the life span and health of multitudes, in addition to bringing vast economic savings to industry and agriculture.

Born in Albany, N. Y., in 1859, he received his first scientific degree, Ph.B., at Cornell, in 1881; and the degree of M.D. at Albany Medical College 2 years-

later. Some 11 universities conferred honorary degrees on him, and he was awarded 7 medals. He was a member of many learned societies in this country and abroad.

Dr. Smith's productive researches began early in life. Several of his most important discoveries were made during the period 1884 to 1895, while he was a young scientist on the staff of the Federal Bureau of Animal Industry. Two years after the beginning of his Government service, in association with Dr. D. E. Salmon, he made important contributions to the knowledge of bacterial immunity. These two scientists found, in 1886, that killed cultures of bacteria would protect animals against subsequent infection with the live organisms. Other investigators developed this knowledge into practical methods of immunization against many diseases. Later Dr. Smith and his associates, Dr. F. L. Kilborne and Dr. Cooper Curtice, studied the biology of the cattle tick. This brilliant trio of investigators proved that tick fever was transmitted solely through a living carrier of the infection, and not, as had been suspected, through mere contact with other animals nor from feed, water, or air. This discovery led to practical measures of controlling and eradicating not only tick fever, but many dreaded human diseases spread by insects and other parasites.

Turning his attention to tuberculosis, Dr. Smith demonstrated for the first time that the germs of the human form of this disease differed from those of the bovine form. At the laboratory of the State Live Stock Sanitary Board of Pennsylvania, it was shown that the bovine type of organism was transmissible to man—especially children.

Dr. Smith was a pioneer in the study of allergy (Theobald Smith's phenomenon), that curious sensitiveness of persons and animals to certain substances. His studies opened up a vast field of research relating to foods, drugs, and biological products.

All these discoveries subsequently led to improved scientific and practical means of safeguarding the health of man and domestic animals. In the later years of his life, Dr. Smith directed the Department of Animal and Plant Pathology of Rockefeller Institute for Medical Research. The results of his researches there also enriched various fields of scientific knowledge. Honored by many professional organizations and institutions, Dr. Smith belongs primarily to the people for whose welfare he so diligently, successfully and unselfishly labored.

LETTER FROM GREAT BRITAIN

ON SHINING EXAMPLES

One of the more common methods adopted by health officers and others engaged in the public service of this country of securing advance or the adoption of some particular scheme or measure is by crying out that it is in operation in some other country. In the pre-war days it was usually Germany that was chosen. Since the war almost invariably the shining example has been the United States, and one says, after the manner of Sterne, "this, that, or the other thing they order so very much-better in America."

In relation to milk, for example, the cry that our practice lagged very far behind the American was so very loud and persistent that tremendous activity developed, and now it is claimed for the milk supply here that it is every bit as good as that of the United States. One respect in which it is admitted with just sadness the British are still behind is in the matter of *per capita* consumption. The amount consumed by each member of the community works out at something ridiculously below half a pint. Even that, however, looks like being put right, and the legislature and everybody else will be much surprised and hurt if within the next year or two the people fail to show themselves a nation of milk drinkers, consuming considerably more than whatever is the maximum amount taken per head in any of the States in the Union. This is to be brought about as a result of a law which received the consent of the King at the end of last session.

MAKING A NATION OF MILK DRINKERS

This is known as the Milk Act, 1934, and among other things it provides for the grant from the national funds of large sums for expenditure on schemes

for improving methods of milk production and of increasing consumption. Incidentally it contains provisions under which school children may obtain milk daily in school for a purely nominal sum, the difference in cost being paid to the retailer through the Milk Marketing Board. This body, which was only recently established for the purpose of securing more equitable conditions for milk producers, particularly, and more even distribution of the article, has also as an aim popularizing and encouraging its wide use. The scheme of providing a cheap supply to school children the Board has taken up most enthusiastically, seeing in it a method of disposing of large quantities of surplus milk that might otherwise prove embarrassing. They welcome the scheme also—as must all who hold milk in high esteem on account of its nutritive qualities—because they believe that it will circulate the milk drinking habit and will insure an increase in the consumption of milk by adults and a raising of the per head figure to something of which no proud patriot need be ashamed and that will compare favorably with, or even overtop, that of America.

In the scheme prepared by the Milk Marketing Board it is provided that subsidy payments shall only be paid if the medical officer of health of the district in which the milk is distributed is satisfied as to the source and quality of the milk supplied and certifies accordingly. In certain areas, including the metropolis, pasteurized milk will be specified and for his half-penny—about one cent—the child will receive one-third of a pint in a capped bottle and a straw through which to absorb it. Already over a fairly large part of the country a voluntary scheme of supply has been worked for some years, so

that there should be no difficulty in putting the nation-wide scheme into operation in the schools this year.

HEALTH IN INDUSTRY IN 1933

The chapter on health in the report of the Chief Inspector of Factories and Workshops for 1933 is as usual contributed by Dr. John C. Bridge, the Senior Medical Inspector. Dr. Bridge, by the way, was recently created C.B.E. or, as the toast-masters describe it, "Commander of the most noble Order of the British Empire," in recognition of the value of the work he has done on behalf of the health of the workers. As always, from the point of view of health officers and others concerned in the preventive side of medicine, the health chapter is the most interesting of the several extremely interesting contributions to the report. On this occasion, so far as general health is concerned, Dr. Bridge finds himself able to report favorably.

Accidents, it is true, were numerous, but this was due to the fact that the numbers in employment were higher and many of those engaged having been off work for so long were, for a time, unaccustomed to the working conditions, machinery, and so on. In other directions the impression gained was that nothing but benefit came to the industrially employed from employment. In order to be quite sure, however, regular medical examinations are felt to be necessary. To these both employees and employers appear to be averse.

A note in the report on the effect on women of industrial work has received a great amount of attention, more especially since the conclusion reached is that, though there is an adverse side to industrial life for women, the general effect is "good—judging from some years of observation in factories—and getting better." Among items on the credit or beneficial side are "the stimu-

lating effects of the discipline and interests attendant on factory life during and after hours, with the higher standard of living that is the wage-earner's. Conditions in factories are, in general, as good and, in many cases, better than those of the workers' environment. The food available at factory canteens and clubs is good, varied and cheap. Factory life certainly raises the standard of personal hygiene among girls." On the adverse side the main effects upon the girls appear to be that "they age quickly; their apparent age is the elder sister to their baptismal certificates. Physical attraction is early attained and quickly lost." The reason given for this is that "women's work often begins when it normally ends. The house and dependents make their claims on the woman worker. Her work is never done."

INDUSTRIAL DISEASES

In the matter of industrial diseases it is noted that cases of poisoning with lead, arsenic, and other metals were fewer than in 1932, as were also aniline and carbon bisulphide poisoning. Anthrax cases, on the other hand, showed an increase, particularly among persons engaged in handling skins and hides, articles notoriously difficult to disinfect.

Special reference is made to the fact that the incidence of epitheliomatous ulceration "now the most menacing of all the industrial diseases that are notifiable," shows few signs of diminishing. Persons working with pitch and tar (in patent fuel works, etc.); with paraffin (in shale oil works) and mineral oil (in cotton mule spinning, etc.) are those chiefly liable. In addition, cancer of various parts occurring among persons working with certain dyes and chemicals and in such places as nickel refining works are giving rise to anxiety. Silicosis and asbestosis, as well as certain new forms of poisoning occasioned by the use of chemicals, many of them

complex in character, of the effects of which on the human subject little as yet is known, come in for special reference also. In the case of asbestosis it would seem that since the introduction of special regulations applicable to the asbestos industry, the problem has been solved. Silicosis and tuberculosis among persons engaged in sand-blasting seems likely also to be conquered in the near future since the discovery that results quite satisfactory may be obtained by substitution of steel grit for siliceous material as an abrasive. The impression obtained from the report is that eventually, in this country at any rate, the use of the latter will be prohibited, except under special circumstances.

DIOXAN POISONING

Among the new forms of poisonings occasioned by the use of complex chemicals, attention is specially directed to that due to the inhalation of Diethylene Dioxide ("Dioxan"). This substance, used in the manufacture of artificial silk for treating cellulose acetate silk yarn, in one instance led to the death of 5 men in one plant, the signs being severe gastric disturbance followed by acute hemorrhagic nephritis leading to suppression of urine, uremia, coma, and death. A most serious view was taken by the department of these cases and eventually the plant in which they occurred was closed and an undertaking given that no further work would be done necessitating the use of Dioxan until all means had been taken to insure safety of the working conditions. Experiments to determine the extent of the toxicity of the material and the precautions necessary to be taken are now in hand. Further, it has been arranged that before any of the new organic compounds now so widely used as solvents, etc., are put upon the market

they shall be tested physiologically for toxicity. Dermatitis among persons engaged in certain industries continues to attract attention and reference is made in the report to the measures of prevention likely to prove effective. One most valuable suggestion offered by Bridge is that there should be regular inspection of workers' hands by a careful observer. In this way, he holds, the necessary precautions are likely to be taken, early signs of skin irritations can be detected and relieved before the resistance of the skin breaks down.

LEGGE'S "INDUSTRIAL MALADIES"

While I am on the subject of industrial hygiene and diseases of factory workers, I should like to refer to a book published here by the Oxford University Press. Written by the late Sir Thomas Legge, one time Senior Medical Inspector of Factories, the work has been edited by Dr. Henry, a Medical Inspector of wide experience in the Factory Department. Sir Thomas Legge was one of the makers of industrial hygiene and, in his day, a recognized authority on industrial diseases. Evidence of the high esteem in which he was held in the United States is to be found in the fact that his work was as well known there as here and on several occasions he was called upon to deliver courses of lectures in American medical schools. The work contains chapters upon most of the industrial diseases and poisonings, as well as upon such matters as notification of industrial disease, compensation, and health and welfare conditions in factories and workshops. Authoritative and informative, Legge's work is to be counted an outstanding contribution to the literature relating to the hygiene of, and diseases associated with, industry.

CHARLES PORTER, M.D.

London

PUBLIC HEALTH EDUCATION*

Comic Strips 40 Years Old—1894 saw the birth of the comic strip. Have we noted the considerable proportion of non-comic strips as the years have passed? Adventure, science, and history have their share of the strips. Why not health? Why should not some of our clever health people devise an idea for real health information to appear in acceptable strip form?

Said *Editor and Publisher* recently:

Entertainment can be combined with more than a little education on the strip page and some artists are doing it well without any attempt to be funny.

"1,820 Ways to Avoid Monotony"
—This is the heading of a page advertisement of an advertising agency, Young & Rubicam, New York. Here is part of the text, the application to health education being left to the reader:

A certain New York business man lives at 58th Street and First Avenue, and has his office at 46th Street and Park.

One day while lunching with a mathematics instructor at Columbia, he chanced to comment on the monotony of his daily walks from home to office.

A few days later, he received a note from the instructor, containing mathematical proof that there were 1,820 routes between his home and his office, all of them different and all the same distance.

Is It Public Versus Private?—In some communities finances have aroused something of a "public versus private" competition for the approval of the public. Probably this arises in the relief field and is less likely in public health. At any rate those concerned with public welfare will wish to look

over the Dec., 1934, issue of *News Bulletin*, Social Work Publicity Council, 130 East 22d St., New York, N. Y. There is a section on what private agencies say about governmental service during money raising campaigns. 25 cents.

Why Not Immunize?—The Santa Barbara County Health Department reports on 355 children between 6 and 15 years old, none of whom had been immunized against diphtheria. The reported excuses from the 164 homes were classified as follows:

Lethargy: 51 (31 per cent), including such answers as: "I will next time"; "Too much trouble"; "All right—if the child wants it"; "Forgot to come."

Ignorance: 26 (16 per cent), including such answers as: "Too young yet"; "Already had diphtheria"; "Wait till exposed"; "Just another fad"; "Not afraid of diphtheria"; "We didn't have it when we were children"; "Never been sick."

Opposition: 84 (51 per cent), including such answers as: "Don't believe in it"; "Made neighbor's child's arm sore"; "Religious objection"; "Poisons the blood"; "Previous unpleasant experience"; "It would hurt"; "Don't like the idea."

Economic Reasons: 1, "Have lately moved here; was not given free where I lived."

Legitimate Medical: 3, "Child has been sick"; "Our doctor (chiropractor) advises against it."

Dr. R. C. Main, county health officer, comments:

It appears, therefore, that our failure to wipe out diphtheria completely is due, in large part, to opposition of the parents. We have learned, however, that this attitude of the parents is not unchangeable. Again and again, by the use of tact and a continuous educational program upon the subject, we have had parents apply for this protection for their children when they had previously bitterly opposed it. Indeed, many of the

* Please address questions, samples of printed matter, criticism of anything which appears herein, etc., to Evert G. Routzahn, 130 East 22d St., New York, N. Y.

children listed in this study have since been immunized.

In *Weekly Bulletin*, California Dept. of Public Health, Sacramento. Nov. 24, 1934.

The Demand for Reader's Time—
A writer addressing printers tells why printers must produce better printing so that more printed matter will be used.

Health agencies buy printed matter to get a hearing for facts and ideas and so they face these same conditions.

Printing in general is not as effective in producing results as it used to be. Why? The answer is to be found in changing conditions, which have brought about a more severe competition for the full attention of readers to whom each piece of printing is to be addressed.

If you want to discover the fundamental reason why printing of a given quality is not doing the job it did 10 years ago, just analyze how you spent your own time for the past 10 days. Schedule, day by day, how much time you devoted to reading *any* kind of printed matter. Deduct from that the time spent on the first page of the newspaper or on a new novel, and you will begin to get some measure of how much of your time is available to those who seek to address sales influencing messages to you through the medium of printed advertising.

Try this same analysis on friends and you will find a like situation. Fume though we may, the radio, the movies, the new streamlined autos, and many other attractions are appropriating more and more of the time formerly available for the reading of printed matter. The cozy evening spent under the lamp, with a variety of magazines, booklets, or pamphlets, is becoming the exception rather than the rule.

The author, Douglas C. McMurtrie, puts this question:

Is printing today as much better and more attractive than the printing we did 10 years ago as the popular-priced automobiles of the present season are improved in style and performance over those on the market 10 years ago?

Let health workers, as well as printers, face the facts:

Printing today, which seizes the few precious available moments of attention, must

be made outstanding in design to attract and to invite the eye. Your piece must be one among a dozen to demand and secure that attention, constantly harder to hold.

When we once get that attention, we must also make better use of it. This means attractive, lively pages, with type intelligently set, so as to interpret the copy story to the reader in crystal-clear fashion. Illustration must be vivid and graphic.

Among the practical suggestions offered, the following may apply to some health material:

There are possibilities in the reduction of size. Any booklet, set sloppily in an indifferent type face and printed on cheap and unimpressive paper, can often be cut a half inch in each dimension, set up with taste and care, and printed on a better quality and more suitable paper, at the same cost and with greater satisfaction to the customer.

When submitting a printing job as we have planned its specifications we may well ask the printer how he would plan it if he "started without limitations."—*Inland Printer*, 205 W. Wacker Drive, Chicago. June, 1934. 40 cents.

"Fight Tuberculosis with Modern Methods"—This, the slogan of the 1935 Early Diagnosis Campaign (EDC), seems the logical follow-up to the preceding campaign themes.

It takes time for new ideas to take root and patience to dispel deeply-rooted fallacies. Yet, we can greatly hasten the acceptance of sound, balanced knowledge through intelligent publicity. Fortunately, public interest in the newer technics of treatment plays into our favor. For these reasons, tuberculosis associations throughout the country have agreed during 1935 to concentrate their educational resources on treatment.

Some may feel that it is quite enough to urge people to go to the doctor and say nothing about treatment. They ask: "Why should the public be informed on treatment?" The first obvious answer is that misconceptions never do any good and it is our job to present the true and modern facts. Another is that an appreciation of scientific medicine is one of the major objectives of health education and the modern treatment of tuberculosis inspires a respect for scientific medicine. A third reason for selecting this theme is that a general knowledge of the treatment

of tuberculosis dispels, to a large extent, the fear of tuberculosis, and prompts the person who may be worrying about his health to go to a scientific doctor rather than to a cultist or to the drug-store. Add to these reasons the demand for a specific explanation of pneumothorax on the part of a limited but increasing number of patients (doctors find it difficult to describe to the non-medical person) and finally the advantage of building up strong public sentiment in favor of the sanatorium.

The weapons of the campaign are of a high order. Four 4-page folders are on dull finish paper, the cover a photograph bleeding four ways with title lines across top and bottom, and with uncrowded text inside. "Modern Weapons to Fight Tuberculosis" contains three times as much text. There are other publications, slides, posters, and motion pictures available. All local tuberculosis associations are supposed to have samples.

It is for the state and local health agencies to make the most of the excellent material provided and the impetus given by the National Tuberculosis Association.

The "Comforter" in Jamaica—
Says Mrs. Smith, in *Jamaica Public Health*, Kingston:

What will the Government be doing next to one's children? First, it's registering 'em as soon as they's born, just like they was so many thoroughbred cattle; then it's sending around a sanitary inspector to have you build a latrine which they say will keep off the bowel troubles and the bad fever; then it's taking 'em to have their hands scratched and be vaccinated so they won't catch de alastrim. Then they tells you to bwoil the milk and water for the little 'uns and not give 'em cerassee tea, and to clean their milk teeth and keep 'em fixed just the same as if they was their second teeth. And when they go to school they have to get their teeth fixed, and they sends 'em home when they get measles or the whooping cough or even the itch; then a man comes to give 'em Government pills to cure 'em of hookworms. And now they're blaming the comforter and say it causes de tb. What will come next? I don't take much stock in such unpractical ideas. I'll bet if de truth known I have

raised more picknies than that Bureau or the Government both put together. Five out of my 8 are living and doing well, except for coughs and colds, earache and toothache, and such natural ailments and ever' single one of them was raised with comforters to keep 'em quiet. Next I looks for de Legislative Council to pass a law indicting honest folks for having typhoid and other God sickness dem. Aunt Eliza Bush-Tea recommend de comforter; she say it keep de gums healthy and she say bush tea and sugar pap is good for babies, too. That Bureau ought to be doing something practical to benefit folks and leave off hadvocating so many high-falutin' ideas them don't have no experience with. That my say!

For the Sunday Newspapers—In July, 1934, Iowa State Department of Health started a special series of releases to the Sunday newspapers of the state.

"Public Health in Fiction" reviews "Silver Linings" a novel by Joseph McCord who made good fictional use of a public health situation, but whose factual material on typhoid was nearly all wrong.

"Can This Be True?" was a series of paragraphs about smallpox, early bath tubs, and other near or far facts or superstitions.

A December 30 release on "The 1934 Health Record" was based on the death records of the first 9 months.

Most of the series is prepared by Dr. J. H. Kinnaman, Division of Child Health and Health Education.

Hygeia for January, 1935—We find a new type of table of contents, each item with a concise descriptive paragraph. We may want to try it on a booklet or an annual report. Then there are articles on

Preventing heart attacks. Sex education for young children. Why condition the air? (Many reasons for it.) These teeth of mine (a new series). The new generation (by a champion). The making and unmaking of a quack (mail order diagnosis). "Occupational diseases" in children (not what it sounds like). Government's interest in violent and sudden death. Overcoming worry (measures

of habit control). Occupational diseases of musicians. Some obesity "cures" and "treatments" (fantastic claims). A.M.A. cheese decisions. Intestinal worms. Diseases of the eye. Tuna fish. Picture section (as usual). New books on health. Questions and answers. School and health: The dominant influence of the teacher. Health teaching in January. Hygiene and the use of the dictionary. Health lessons in a rural school. How shall we teach safety? New health books for teachers.

Help in Preparing a Teachers' Health Year Book—From the National Education Assn., 1201 16th St., Washington, D.C., comes this request:

The Department of Classroom Teachers of the National Education Association has in preparation a yearbook dealing with the health of the classroom teacher—physical and mental.

Please direct our attention to any published material that you regard as especially helpful in the field of teacher health. We would appreciate greatly the receipt of any pertinent materials not generally available in libraries, such as leaflets or mimeographed reports. If important research projects relating to teacher health are under way, please describe briefly what your organization is doing or let us know where to obtain the information.

We should be glad to have you refer to outstanding contributions from other sources.

Reply to Ivan A. Booker, Research Division.

Optimism Needs Correction—One of our special correspondents, reporting on observations at Pasadena, mistakenly mentions the recent passage of a mattress regulation in Baltimore.

Dr. Huntington Williams reports that

As far as I can find out, there has been no new regulations in this matter in Maryland since 1931, nor has there ever at any time been any regulation or law for the city of Baltimore as such.

This refers to "What We Noticed at Pasadena" in Dec., 1934, issue.

Das Wunder Des Lebens—Dr. Bruno Gebhard of the German Museum of Hygiene, has sent us the announcement of an exhibition called "Das Wunder Des Lebens," which is to take

place in Berlin from March 23 to May 5, 1935. The substantial booklet describing the exhibition is illustrated with strikingly colored and most original photographs and drawings.

Through pictures and text the human body is brought into relation to elements in nature, to outdoor life, to industry—to the whole of life. Keeping well becomes an exciting adventure.

Health Education in Massachusetts—A "Health Education" issue of *The Commonwealth*, Massachusetts Dept. of Public Health, July-Sept., 1934, provides a review of much of the thinking as to health education and its actual practice in Massachusetts. Several times we have given up the attempt to review these 72 solid pages of varied material. So much of it has a bearing in all parts of the country that copies sent to state and local health agencies should be carefully preserved and made available to all health workers in the state or community.

Here are some topics:

Prerequisites of a progressive health educator; health department bulletin; a local health association; what a large city health department does; in the Y.W.C.A.; a hospital dispensary; in mental hygiene; prenatal and postnatal letters and other printed matter; school lunch; demonstration or example by display; home-made posters and charts; exhibits; in the schools; supervisor of health education; classroom teacher; physical education; preparation or material for school use; junior high school course; the health forum (radio); visual methods.

Health Education in a Small City—This topic was presented at a joint meeting of Canadian Public Health Association with two other groups by Dr. D. V. Currey, Medical Health Officer of St. Catharines, Ontario.

Dr. Currey said:

... the further one enters this field of endeavor the more he realizes his opportunities and finds that no one method is entirely satisfactory, but that the combination of plans will give the best results. There is no doubt

that all public health teaching must be positive, nontechnical, and, above all, interesting.

He then discussed the practical use of public addresses, newspaper publicity, bulletins, pamphlets, motion pictures, exhibits, hospital day, direct to the home, parades, and broadcasting.

Health education of the public should be the most important duty of any health officer and should be part of every health program.

Each member of the department of health staff should continually be on the lookout for new ideas, new types of posters, etc., which may be used for the purpose of educating the public.

—*Canadian Public Health Journal*, 105 Bond St., Toronto 2, Ontario. Nov., 1934. 35 cents.

To Meet School Health Leaders in Europe—The Health Section of the World Federation of Education Associations is arranging a European travel and study tour in connection with the Federation meeting at Oxford, England, August 10-17, 1935. Leaving New York, June 29, the tour will visit France, Switzerland, Germany, Poland, Russia, Finland, Sweden, Denmark, and England. The group will meet the leaders in school health in each of these countries. For further information, write to the chairman of the Health Section, Professor C. E. Turner, Massachusetts Institute of Technology, Cambridge, Mass.

RADIO

The Massachusetts Dept. of Public Health radio program for Oct.-Dec., 1934, was in three sections:

"Health Messages," 4:30 p.m., Wednesdays, Station WBZ, papers prepared by members of Massachusetts Medical Society; "Health and digestion . . . Old age deferred . . . Appendicitis . . . Hospitals . . . Gall bladder trouble . . . Prenatal care . . . Anemia and its treatment . . . First aid . . . Protecting the school child from fatigue and strain . . . Abdominal pains . . . How surgery and advances . . . Angina Pectoris . . . Arthritis."

"Health Review," 1:30 p.m., Tuesdays,

Station WEEL, historical sketches by Eleanor J. Macdonald: Edwin Chadwick . . . The contribution of Edwin Chadwick to Public Health . . . Lemuel Shattuck . . . The report of 1850 . . . The report of 1850 continued . . . The 1869 Board of Health and vital statistics . . . The State Board of Health, lunacy and charity and the re-establishment of the State Board of Health . . . The State Board of Health . . . Massachusetts Dept. of Public Health . . . Water . . . Methods of obtaining water through the ages . . . Modern methods of obtaining a pure water supply . . . Pure water and filtration.

"Health Forum," 5:00 p.m., Fridays, Station WEEL, short topics requested by radio audience on health matters by Lila O. Burbank, M.D.

Recent broadcasts by Minnesota State Medical Assn. (Station WCCO, Tuesdays, 10:45 A.M.):

Diabetes in Minnesota . . . Blood transfusions . . . Progress in public health . . . Warts and moles . . . Encephalitis.

Station WIXAL is the short wave, non-commercial station, "dedicated to enlightenment." You will find it between DJC, Berlin, and GSA, Daventry. 6040 kc. For program address World Wide Broadcasting Corp., University Club, Boston, Mass. No health topics as yet, but we will expect them in due season.

Station W.H.Y. is the way station names are spelled, with periods, by some health and welfare workers. But in actual practice the form is Station WHY, that is, without periods.

SCHOOL HEALTH EDUCATION

A \$500 scholarship in health education, at Massachusetts Institute of Technology, 1935-1936, is available for women only. Write to National Tuberculosis Assn., 50 W. 50th St., New York, N. Y.

"A Project in Rural School Health Education," by R. E. Grout. Reprint from *Milbank Memorial Fund Quarterly*, 40 Wall St., New York, N. Y.

10 cents. Building the program in Cattaraugus County.

"State-wide Trends in School Hygiene and Physical Education," by J. F. Rogers, M.D., Office of Education. Revised. Supt. of Documents, Washington, D.C. 5 cents.

MATERIAL WANTED

E. Kohler, George Williams College, 5315 Drexel Ave., Chicago, Ill., writes:

Our class in health education at George Williams College is composed largely of teachers and leaders in social work. We are interested in any material available on health education and would appreciate having copies of any free health material you may have or lists of publications if free material is not available for all.

BULLETINS AND JOURNALS

"Know Your Health Department" is a series of brief sketches, with photographs of staff members. In *Birmingham's Health*, Birmingham, Ala.

Michigan Out-of-Doors is now *Health*, issued by Michigan Tuberculosis Assn., Lansing.

"Millions of Names" tells about the state registration of vital statistics. In *Weekly Bulletin*, State Dept. of Health, Sacramento, Calif.

Prize winning stories from the recent contest conducted by *Journal of Outdoor Life*, 50 W. 50th St., New York, N. Y., are being published in that magazine, starting with Dec., 1934, issue. 15 cents an issue.

Wolverine Health Bulletin, Michigan Tuberculosis Assn., Lansing, Mich., is issued for school room use. Monthly, two parts of 4 pages each.

A full-page picture of a child "bleeds" over all four sides of the page, on cover of the November, 1934, issue of *Everybody's Health*, 11 W. Summit Ave., St. Paul, Minn. 10 cents.

On the cover page of this issue of *Health* (in center of a big white space) appears the number 2,309,513,600, a sum almost too large for the mind to appreciate. This figure repre-

sents the number of heart beats that the average New Havener may anticipate during his lifetime under present conditions of living and based upon the life expectancy which is, at birth, a little more than 60½ years.

The above from *Health*, New Haven Dept. of Health, was followed by a brief application. A striking detail for a health bulletin, but we think that it would have been more effective if the explanatory paragraphs had been made more conspicuous. They were buried at end of an article not related to the cover-page figures.

FOR EDUCATION OR REFERENCE

"The Costs of Tuberculosis with Special Reference to the Adequacy of Medical Care and Treatment," by R. A. Seder. National Tuberculosis Assn., 50 W. 50th St., New York, N. Y. 35 pages. 20 cents. A study suggested by Committee on the Costs of Medical Care.

If there is a slum clearance movement in your city the leaders will be glad to receive from you a copy of "An Analysis of a Slum Area in Cleveland," prepared "with the counsel of Howard W. Green," of the Public Health Education Section, 1900 Euclid Ave., Cleveland, Ohio. 60 cents. Shows how much it "costs government and society to maintain a slum."

Julius Rosenwald Fund, 4901 Ellis Ave., Chicago, Ill., has 8 posters, 20" by 30", enlargements of the picture book charts on costs of medical care. Posters are sold for \$4.50, or will be loaned. A copy of the picture book is free.

"Mortality Experience of First Nine Months of 1934," and "Geographic Distribution of Mortality" in *Statistical Bulletin*, Metropolitan Life Ins. Co., New York, N. Y. Oct., 1934. Free.

"Protected from Harm" is a 4-page folder on diphtheria from the Milwaukee, Wis., Health Department. It is an effective straight-forward presentation emphasizing that "most of the

school children" and "many of the children below school age" have been protected. Please enclose 3 cents postage with a request for sample.

"A 'Recovery Act' for the Handicapped," by Edward Hochhauser, 71 W. 47th St., New York, N. Y. Values of the "sheltered work shops," Enclose 3 cents postage.

"Twenty-Five Years History of the Ohio State Sanatorium" is reprint of articles by R. G. Paterson, 72 S. 4th St., Columbus, Ohio. Enclose 25 cents postage.

Two chapters in "The Man with Bated Breath" are devoted to the physical and mental effects of smoking marijuana.

"What You Should Know about Tuberculosis" is a 30-page "handbook for tuberculosis patients." With substantial cover, good type, wide leading, and distinctive headings the pamphlet looks easy to read. Every right hand page carries a line cut which bleeds to the center and the top of the page. Obtainable through the national and other tuberculosis associations. You will want to know about tuberculosis when you see this pamphlet.

Good material for bulletins and other uses is offered in the Nov., 1934, issue of *Statistical Bulletin*, Metropolitan Life Insurance Co., New York:

The chances of celebrating a golden wedding (as well as tin and silver weddings); 3,000 persons killed annually in shooting accidents; insect-borne diseases can be eliminated.

If you have need for information about the Women's National Health Council write to National Health Council, 50 W. 50th St., New York, N. Y. The "Council" is promoted by L. Ellis Evons, advertised as a "professor, noted biologist and sexologist."

"Leprosy: Observations on Its Epidemiology in Hawaii," by U. S. Public Health Service. Dept. of Documents, Washington, D.C. 5 cents.

"Meat Dishes at Low Cost." U. S.

Dept. of Agriculture, Washington, D.C. Another contribution from the Bureau of Home Economics, Supt. of Documents, Washington, D. C.

A monthly clip sheet free, based on magazine articles, is supplied by *Hygeia*, 535 N. Dearborn St., Chicago, Ill.

"Out of Babyhood into Childhood." Children's Bureau, Washington, D.C. 8 page folder. Habits and care of the 1 to 6 year old. *Free*.

"Publications on Low Cost Diet." Revised edition of list of publications for reference and for distribution—for administrators, workers, clients. Social Work Publicity Council, 130 East 22d St., New York, N. Y. 10 cents.

"Reduction in Health Department Activities" is the "round table" subject in June and July, 1934, issues of *Municipal Sanitation*, 24 W. 40th St., New York, N. Y. Single copies, 25 cents. Many health officers answer 4 questions, and show how essential work is carried on despite decreases.

Reprints from *Journal of Social Hygiene*, 50 W. 50th St., New York, N. Y., at 10 cents for single copies:

"High Points of the Conference on Education for Marriage and Family Social Relations." 12 pages.

"Betrothal," by P. Popenoe. 8 pages.

"What Every Person Should Know About Milk," by L. S. Frank. Discusses: Why is milk such an excellent food, and how much of it should be included in the diet? How can milk be safeguarded to prevent it from transmitting disease? How can consumers be certain that milk they drink has been thus safeguarded? *Public Health Reports*, U. S. Public Health Service, Washington, D.C. Dec. 14, 1934.

NEWSPAPERS

"Smite the Mite" is an Iowa State Dept. of Health news release on scabies.

Vital statistics for 1933 were highlighted in a news release from the New

York State Dept. of Health, with this "lead":

Babies born in New York State today have a far better chance of surviving the first year of life than did those born 25 years ago.

"Efficient Health Service Safeguards People's Welfare" is a page-wide headline at the top of a special section of a holiday edition (Dec. 15, 1934) of *Hamilton Spectator*, Hamilton, Ont. Of special interest is "Mr. Average Citizen Hears about Hospital" in which "John Brown, one of Hamilton's younger business men" was struck by a car, and becomes acquainted with the hospital. Happily John had an inquiring mind, and all staff members who served him were on the job of informing the patient. Other cities might well use the idea.

An editorial and a cartoon in the same newspaper resulted from a recent news release. The news release was based on material in a current issue of *Health News*, New York State Dept. of Health. The subject was the decreased maternal death rate in the face of an increased birth rate. The cartoonist and the editorial writer served the *Albany Evening News*.

To understand that marvelous medium, the newspaper, which plays so large a part in adult health education, one needs to visit a newspaper plant. An illuminating supplement to an actual visit to any newspaper is "News: The Story of How It Is Gathered and Printed," issued by the *New York Times*, West 43d St., New York, N. Y. By picture and text this pamphlet will make clear much that is not obvious in the personal visit to a newspaper office. *Free*.

WHAT OTHERS HAVE DONE

The holiday spirit, Christmas, and New Years were utilized by bulletins,

news releases, and special cards from various departments and associations.

Several state-wide Home Hygiene Days were sponsored in recent months by the American Red Cross. *The Red Cross Courier* suggested that store window demonstrations be featured.

"Scientific Eating Campaign at Stephens College," by T. Rose. *Journal of Home Economics*, 101 E. 20th St., Baltimore, Md. Nov., 1934. 30 cents. Plan for "Scientific Eating Week" in a college.

"Cancer Prevention Week in Quebec," by Dr. E. Couillard. *Canadian Public Health Journal*, 105 Bond St., Toronto 2, Ontario. Sept., 1934. 35 cents.

In the exhibition the technic of microscopic examination of tissues was suitably demonstrated in the following manner. The visitor, after being shown a microscope, was directed by an arrow to three excellent displays of micro-photographs, in natural colors, of cancerous lesions, including lesions of the central nervous system, various organs, the bones and skin. These micro-photographs, on glass, were illuminated, permitting of examination as transparencies. . . . Gross pathological specimens of cancer were exhibited in the center of the room, showing lesions of all the organs of the body. Special attention was paid to the arrangement of this portion of the exhibit, so that lay persons might better understand the nature of cancer. . . . The visitors were conducted through the exhibit by physicians from the university hospitals.

The widespread distribution of blotters and cards was a feature of the week. The advertising cards, whether large or small, the blotters, and the other literature presented an allegory of cancer, which was represented by the figure of a crab. In this picture the crab, in striking green or red color, casts its shadow ahead, but its forward progress is impeded by a sword, the symbol of surgery, and by a lightning-like ray, a symbol of electricity and radium. Two crabs of gigantic proportions adorned the side panels of the entrance to the hall. Constantly used in the advertising and publicity was the message, "Kill Cancer before it Kills You," conveying in a striking manner the keynote of the "Week"—the prevention of cancer deaths.

BOOKS AND REPORTS

American Medicine—By Henry E. Sigerist, M.D. New York: W. W. Norton & Co., Inc., 1934. 436 pp. Price, \$4.00.

There is a certain satisfaction in finding a book by a prominent author which one can safely advise one's colleagues it is not necessary to acquire. In this instance the reason is simple, and inherent in the fact that while there is some history in certain chapters, the bulk of the volume is a digest of recent, or at least contemporary, publications, quite familiar to physicians and others reasonably well read in the professional, social, educational, and preventive aspects of medical art and science. *American Medicine*, in 286 pages, was written for German consumption, and while doubtless quite appropriate for that purpose, constitutes something of a surfeit in its translated form.

One is led by the jacket to anticipate a formidable treatise: "The rise and progress of American Medicine from the earliest times to the present," and, knowing the traditional thoroughness and meticulous methodology of such masters of history as Sudhoff and Harrison, to search for nuggets of newly mined gold of real merit from their colleague and pupil, the junior historian, author of this volume.

In the introduction we are told that "four years of intensive studies" went to the product of this book, and on the last page we read, "This book kept me busy for four years," and yet we find that the author first visited this continent in September, 1931, and the text after completion in German in the winter, 1932-1933, was translated with-

out change, other than minor corrections, by May of 1934.

We have read Dr. Sigerist's *Great Doctors* and *Man and Medicine*, and hope we may have in due time *Russian Medicine*, which he announces, but it was hardly worth while to offer to physicians in the United States quite so large an aggregation of medical abstracts in so casual a descriptive form as this *American Medicine*.

Of the 9 chapters, the first 3 on the Indians, the discovery and conquest of the Americas, on the colonial settlements and their separate and characteristic hardships, and on the United States down to date, give us a pleasant sketch, as it were, gleaned from John Fiske, George Trevelyan, and James Truslow Adams, and quite in the best manner of a good school book, and quite picturesque as a background for the "Pioneer" chapter which follows.

While regional and provincial preferences might differ, there will be general unanimity of belief that the 11 physicians picked as our profession's pioneers are well chosen, from Morgan and Rush, through McDowell, Drake, Beaumont, Gross, and Sims, to the giants of our day, Holmes, Mitchel, Billings, and Osler. This is a good chapter and shows a sincere appreciation based on wide reading and much listening. One searches in vain for references to the story of great physicians well known of in our neighbors' Dominion.

Some explanation of a quite understandable predominance of illustration from the now well-worn story of Johns Hopkins appeared necessary, even to the author, for we find on page 146, "I

shall give the greatest space to describing the set-up of Johns Hopkins University, not only because I am most familiar with it, but because I have the impression that there has been found the most successful solution." We may wonder whether always, and in the continuing product, the verdict of the future will be the same as to solution.

The gist of chapter 5 is a general reflection of the Flexner and subsequent A.M.A. Council reports. As a contemporary visitor telling his home folks what he read or heard in the United States, it is brief and to the point. In the 34 pages of chapter 6, we are led hurriedly through the Rappleye and the Committee on Costs of Medical Care reports, stopping briefly to touch on distribution of physicians, group clinics, costs, insurance, the A.M.A., and the medical arts. Similarly, in chapter 7, we skip along with short comments on hospitals, old and new, the American College of Surgeons, hospital finances, social workers and nurses, all of which take but 25 pages.

Preventive medicine in America requires 36 pages to deal with city, state, and federal health services, often ignoring important origins, dating Child Hygiene as late as 1915, and then giving a passing word to a few communicable diseases, the White House Conference on Child Health, sterilization, mental hygiene, and periodic health examinations.

The last chapter devoted to Medical Science leads to the conclusion that "The beginning of the place of the United States in Medical Science was in 1893 when at Johns Hopkins Medical School was established a scientific center of first rank, and with it a beginning of organized research."

New Yorkers must forget their Prudden, Delafield, and Park, and other cities their scholars of other years, in the face of the above authoritative opinion!

The translation of *American Medicine* for sale in this country would seem to add little to the convenience or the substance of contemporary publications.

HAVEN EMERSON

Dynamics of Population—By Frank Lorimer and Fredrick Osborn. New York: Macmillan, 1934. 461 pp. \$4.00.

Dynamics of Population is divided into four parts:

Part I, Population Trends of American Groups, covers the trend of the total population and reproduction trends by race, nativity, occupation, and economic status. The conclusions of Part I state that there is no marked difference in the net reproduction rates between whites and Negroes, whereas there seems to be high fertility in the other racial groups: Mexicans, Japanese, Chinese, and American Indians. There also seems to be a tendency to lowered fertility as "foreign" groups become "native," that is, after the second generation in this country. Once the foreign group adopts the American customs the problem of fertility becomes regional or social.

Part II, Measurable Characteristics of American Groups, deals with the variation in physical development and health of American groups, the variation of cultural-intellectual background among racial and regional groups, and groups classified by occupation and social status.

Part III, Influence of Differential Reproduction on the Characteristics of the American People, covers the social and biological influence on fertility. The conclusions on this section state that, at present, there is a negative association between fertility and cultural-intellectual level which if allowed to go on, threatens to defeat the aims of the whole public educational movement. A slight increase in the reproduction rates in the higher intelligence group and a

correspondingly slight decrease in the reproduction rate of the groups with lower than average intelligence would materially decrease the number of feeble-minded and increase the number of individuals of higher intellectual capacity. At present this is just the opposite.

Part IV, *The Causes and Control of Population Trends*, covers the physical, medical, social and economic factors affecting fertility and a discussion on the possibilities of social control. In groups with a high standard of living and a knowledge of contraceptive methods, there must be social conditions that are very favorable to fertility to keep the group self-replacing. It was also found that higher education of women tends to delay marriage but education is not a factor in lowered fertility among married women. There is, however, a negative association between full-time gainful occupations for women and fertility.

In conclusion the authors state:

Population trends have run their course in the past with little attention by anyone to their momentous influence on human destiny. Variations in fertility, although immediately controlled by individuals, are indirectly determined by particular social factors. It is evident that the social conditions which affect reproduction might be modified in a number of ways, so that the dynamic influences of population change would be more in line with conscious social objectives. Eventually, if our dream of human progress is to be realized, rational social action must replace the operation of blind forces in this as in other fields. In the furtherance of this ideal there is need both for more exact science and for a larger appreciation of the possibilities and values of human life.

There are a great number of charts and tables throughout the text—126 tables and 54 charts, all of which are from reliable sources. The book is well indexed and includes a glossary and complete bibliography which will be of particular interest and help to students of sociology.

E. J. CROSS

An Activity Analysis of Nursing—

By Ethel Johns and Blanche Pfeferkorn, New York: Committee on the Grading of Nursing Schools, 1934. 214 pp. Price, \$2.00.

This book reports one of the projects recommended by the Committee on the Grading of Nursing Schools to be listed on the Five-Year Program adopted in 1926. The committee felt that before nursing schools could be assisted in preparing good nurses, it needed to discover what good nursing is and how it can be taught.

The first chapter tells us what good nursing is, and is a classic. The information in it may be put to many uses. The great variety of men in all occupations invited to make commencement addresses in nursing schools can obtain here a fine background for writing their papers. Those physicians ever with us who still think nurses are receiving too much education to be useful will get an eye-opener.

The analysis which follows the first chapter is a revelation. It was time someone did a little research to find the depth to which the teaching of the fundamental sciences to nurses should be carried. In Chapter VII a possible technic is suggested which may prove useful as a practical demonstration of the direct relation to actual nursing procedure of the technic of science. For this purpose attention is concentrated on pneumonia for the disease, and anatomy and physiology for the subject taught.

One becomes a little more thoughtful about nursing as he reads the list of 12 nursing aspects which were selected for classification as they relate to conditions requiring nursing care in the hospital and community.

Although this book is most valuable to those interested in teaching and making the curriculum for nursing schools, there is meat in it for all in any way concerned with good nursing.

The book is written in a scholarly manner and is a really scientific book, in our opinion. EVA F. MACDOUGALL

The Adolescent in the Family: A Study of Personality Development in the Home Environment—Publication of the White House Conference on Child Health and Protection. New York: Appleton-Century, 1934. 470 pp. Price, \$3.00.

This volume presents the report of the Subcommittee on the Function of Home Activities in the Education of the Child, of the White House Conference on Child Health and Protection. Its format and method of presentation is similar to other publications appearing in this series.

A serious attempt is made "to obtain a picture of the present-day American family functioning as an environment for child development." The study was based upon carefully prepared questionnaires obtained from 13,000 public school children of junior high school age, about 8,000 of whom were selected for detailed study. Several hundred teachers contributed to the study by filling out a rating scale for each pupil.

Part I compares white American, Negro, and immigrant children from the standpoint of rural and village life. Such factors as socio-economic status, the broken home, social isolation, religious training, confidential relations between parents and children, etc., are considered in the light of the data obtained.

Part II considers the personality of the child and the family background, taking up the status of the family, family activities, health regulations, sex education, types of successful and unsuccessful families, and parent-child relations, and family education.

The appendix is replete with detailed comparative tables, a thorough discussion of the methods used in the study, and copies of the questionnaires. One

of the most valuable parts of the book is the number of case histories scattered throughout the text to illustrate various phases of the subject.

Two the findings stand out clearly and may be mentioned here:

The externals of home life, like its economic status or its housing arrangements, while important, are not nearly so significant for personality development of the child as are the subtler and more intangible aspects of family life, such as affectionate behavior, relations of confidence, inculcation of regularity in health habits and reactions to the illness or nervousness of parents. . . .

The average level of family relations and of personality adjustment of the children is somewhat higher for urban than for rural children. . . . If it stands the test of further inquiry, it indicates the validity of the assertion that the loss of certain economic and other functions from the home makes possible the more harmonious organization of family life upon a cultural and affectional basis. It may also show the result of the greater effect of child study and child care movements in the city than in the country.

One cannot read this volume thoughtfully without being impressed with the profound changes which have come over the American home in one generation. Many of our present-day socio-economic problems are closely lined with adolescent-child-family relationships and an intimate knowledge of these should help us in making the new adjustments necessary. RICHARD A. BOLT

The Advance of Science—Edited by Watson Davis. New York: Doubleday, Doran, 1934. 400 pp. Price, \$3.50.

It would indeed be a bold man who attempted a critical review of this book. It covers subjects ranging from the cosmic ray and the smashing of the atom to evolution, race betterment, and human behavior. There may be individuals who are competent to speak knowingly on all of the subjects treated, but the reviewer is not. The editor, who is in constant touch with all the leading sources of scientific knowledge

in this country as well as Europe, has called to his assistance upward of 60 specialists to whom he has given credit for coöperation and advice. The names are a guarantee of the accuracy of the statements made.

Even those who keep in touch with the advancement in science will be astonished at what has been collected within the 390 pages of text. It is well written in an interesting manner, and is therefore easy to read, even though some of the subjects discussed are very abstruse. There are useful tables giving the glands and their hormones, the vitamins as far as known, and other subjects which are being mentioned more and more frequently in the daily press.

The book is abundantly illustrated, though some of the illustrations appear to the reviewer to be misplaced. For example, it is hard to see why the photographs of lightning, electric sparks, spectrum of a meteor, or a mercury boiler drum should be put under the head of *The Fight Against Disease*. We judge that this is economic, as space on these same pages is given to the new giant X-ray tube and the picture of Johnny who roller-skated just after his first birthday.

There is a glossary of new words in science, some of which do not seem to be new enough to find a place in this book. A table of Atomic Weights, the Metric System and its conversion into the English system, comparison of the thermometer scales, and diagrams of the Heavens in several seasons of the year are given. The book is a mine of information and should be welcomed in every library and by all readers. The volume ends with a good index which assists greatly in its use.

We can only add that it is with a good deal of pride we note what has been done in America. It is not too much to say that American scientists are now the equals of those in any part

of the world. We back this statement by calling attention to the Americans who have won the Nobel prize in the last few years. MAZÏCK P. RAVENEL

Human Nature. A Guide to Its Understanding—By Judson Rea Butler. New York: Greenberg. 174 pp. Price, \$2.00.

This book aims to be a guide to the understanding of human nature. It is written in a style which is interesting, and numerous examples facilitate understanding by the layman. Varied topics are included in an extensive discussion of the partial identity principle, by which "Any part of a situation which causes a definite act may later call forth the same response, either in whole or in part." Subjects range from child training to mental hygiene, from habit-control to hypnosis. IRA V. HISCOCK

Medical Diseases for Nurses—By Arthur A. Stevens, M.D. and Florence Anna Ambler, R.N. (2d ed.) Philadelphia: Saunders, 1934. 513 pp. Price, \$2.75.

This book has the earmarks of a successful text. It represents the joint thinking of a physician and a nurse. It is written simply and directly, without any superfluous words and with excellently marked headings. The lack of illustrations does not seem to detract from its value.

Pneumonia which according to *An Activity Analysis of Nursing* seems to be one of the most frequent diseases to need nursing care both in hospitals and in the community, is given a great deal of attention.

As in the old edition, each disease is treated under the following captions: definition, etiology, symptoms, pathology, complications, prognosis and treatment. There is not an omission anywhere, and all details are treated clearly.

Our only criticism is of a paragraph

dealing with the nursing care of tuberculosis which says "During the night all windows should be wide open no matter how cold it is or how stormy." We feel that in the best tuberculosis hospitals today there is not nearly as much emphasis on cold air. Some of the newer tuberculosis hospitals are even being built several stories high, with hardly any balconies—the buildings resembling hotels.

It seems that with so much emphasis as is being put on prevention, a paragraph on how to prevent each particular disease might be inserted. This is covered somewhat under Etiology, but on the negative side.

We recommend this book and shall keep it close by to draw on both in our professional relationships and in those personal ones in the home and among our friends. EVA F. MAC DOUGALL

Rules for Recovery from Tuberculosis—By *Lawrason Brown, M.D.* Philadelphia: *Lea & Febiger*, 1934. 275 pp. Price, \$1.75.

In the treatment of tuberculosis the good doctor teaches the patient to help himself. Dr. Brown's book, designed specifically for the tuberculous patient, was perhaps the earliest of its kind. It grew out of his practice of conducting a "question box" hour for the patients at Saranac Lake. For years it has been a best seller. Patients by the thousands have read and re-read it and kept it for reference. Its kindly, cheerful tone and a certain charm of style have won for it the designation of the tuberculosis patient's bible. The 6th edition is a complete revision, which adds about 30

pages. Special attention is given to collapse therapy, after-care, and social readjustment of the patient. The vaccination of children to prevent tuberculosis, a discussion of special diets so much written about lately, the use of alcohol and tobacco, also receive emphasis.

The book is compact in size, printed in large type and has a bibliography and a good index. H. E. KLEINSCHMIDT

The Art and Principles of Nursing—By *Amy Elizabeth Pope, R.N., and Virna M. Young, R.N.* New York: *Putnam*, 1934. 832 pp. Price, \$2.75.

Section I, 662 pages, of this text deals specifically and definitely with the technic of professional nursing. In addition to the topics usually discussed in texts in this field, it has a chapter on Hydrotherapy and Heliotherapy, and one on the various tests so much used in modern medicine as a means of diagnosis.

The discussions and descriptions of technics are done carefully and concisely. They contain not only directions as to the technic itself, but as to the equipment needed, the reasons for precise procedures, and the precautions to be taken in special types of cases.

Section II is devoted to a discussion of diseases, types, causes, and special nursing care.

This text is evidently based on experience, is interestingly written, and concise. It is well worth the careful study of nurses, and, since it indicates the standard nursing procedure in various diseases, might well be read by physicians.

CHARLES H. KEENE

A SELECTED PUBLIC HEALTH BIBLIOGRAPHY WITH ANNOTATIONS

RAYMOND S. PATTERSON, PH.D.

Practical Prenatal Hygiene—Nine methods of approach the public health nurse may use in maternity case-finding.

ANON. Maternity Case-Finding. Health News, New York State Department of Health 11, 49:194 (Dec. 3), 1934.

The Doctor and the Public Health Nurse—Reiteration of the fact that organized medicine does not know the public health nurse and why. Yet the relationship between the medical and nursing professions is recognized by leaders in both groups as the most important factor governing the success or failure of a public health nursing program.

BLUMENTHAL, R. W. Organized Medicine and the Public Health Nurse. State Board of Health Bulletin, State of Wisconsin, 5, 20:3 (Dec.), 1934.

Vitamin Milks—Milk fortified with vitamin D is a valuable way of administering the needed vitamin to infants, to expectant, and possibly to nursing, mothers. That it is of value to normal adults or that it may have undesirable after-effects, only time will tell.

BUNKER, J. W. M. and HARRIS, R. J. The Clinical Status of Vitamin D Milks. New Eng. J. Med. 211, 25:1140 (Dec. 20), 1934.

For the Better Diagnosis of Syphilis—A scheme, by which blood samples will be sent to serologists who have developed diagnostic tests for syphilis, has been undertaken to appraise the various modifications of complement fixation methods and flocculation tests.

CUMMINGS, H. S. *et al.* The Evaluation of Serodiagnostic Tests for Syphilis in the United States. J.A.M.A. 103, 22:1705 (Dec. 1), 1934.

About the Phage—In this review of the bacteriophage phenomenon, while dealing largely with therapy, the value of which the authors seem to doubt, the bacteriologic and immunologic parts of the discussion will be of interest to sanitarians.

EATON, M. D. and BAYNE-JONES, S. Bacteriophage Therapy. J.A.M.A. 103, 23:1769 (Dec. 8), 1934.

Milk Safeguards—Facts that the public should know about milk (with which every sanitarian must be familiar) include, of course, the discussion of an adequate milk control ordinance. Consumers are stimulated to see that theirs equals the U.S.P.H.S. Standard and that it is enforced.

FRANK, L. C. What Every Person Should Know About Milk. Pub. Health Rep. 49, 50:1505 (Dec. 14), 1934.

Evidence of Brucella Infection—In those departments of packing plants in which cows are slaughtered, as high as 80 per cent positive reactions for brucella infection were found among the workers, although no histories of frank undulant fever could be elicited. Some cases did occur among those working with hogs. The incidence of the allergic state varied with the length of employment.

HEATHMAN, L. S. A Survey of Workers in Packing Plants for Evidence of Brucella Infection. J. Infect. Dis. 55, 3:243 (Nov.-Dec.), 1934.

Bed Rock Public Hygiene—The essentials of adequate public health administration, so familiar to sanitarians, are set forth briefly and convincingly.

HISCOCK, I. What Is an Adequate Health Program? *New Eng. J. Med.* 211, 25:1153 (Dec. 20), 1934.

Food-Borne Streptococcic Poisoning—Green-producing streptococci isolated from an offending cream pie yielded a filtrate causing typical symptoms of food poisoning when fed to monkeys. Green-producing streptococci from other sources like infected teeth and feces likewise produced toxic filtrates.

JORDAN, E. O. and BURROWS, W. Streptococcus Food Poisoning. *J. Infect. Dis.* 55, 3:363 (Nov.-Dec.), 1934.

Breast Milk Distribution—How breast milk is collected and dispensed to babies needing it in New England is told in the first of two papers. How the supply and demand is controlled and met will be told in a succeeding paper.

KEENE, H. M. Maternal Milk Collection. *Pub. Health Nurs.* 26, 12:649 (Dec.), 1934.

Rheumatic Fever in Children—Children's hearts are especially susceptible to rheumatic infection, and heart disease in patients under 20 is rheumatic in origin. Treatment can prevent permanent damage.

LYON, J. A. Rheumatic Heart Disease in Early Childhood. *New Eng. J. Med.* 211, 26:1185 (Dec. 27), 1934.

"They Shall Not Starve"—Another paper indicating that average weights of children in 1934 do not differ significantly from pre-depression averages. Evidently, in the district surveyed, the children of the poor were fed enough at least to grow at the usual rates.

PALMER, C. E. Further Studies on Growth and the Economic Depression. *Pub. Health Rep.* 49, 49:1453 (Dec. 7), 1934.

Perhaps You May Know all about This—Of no immediate importance to sanitarians, but still most interesting is

this observation: some red blood cells have hair-like processes which exhibit a rapid whip-like motion. They may be retracted back into the cell or they may be broken off to continue their motion for a while after being detached. Later they may take on a beaded or granular appearance. The method of staining to show this phenomenon is described.

OLIVER, W. W. Staining of the Processes (Flagella) of Human Erythrocytes. *J. Infect. Dis.* 55, 3:266 (Nov.-Dec.), 1934.

Buying Medical Services—A whole issue of the *Survey Graphic* is given over to discussions of social medicine by an economist, a publicity man, physician, surgeon, dentist, nurse, hospital superintendent, a sanitarian, and others. An inclusive collection of essays useful to proponents of group payment for medical services.

ROSS, M. The Issue of Health. *Survey Graphic* 23, 12:581 (Dec.), 1934.

Colds vs. Vitamins—Vitamin A, the so-called "anti-infective" vitamin, has no effect upon the incidence or severity of colds. This bit of research will hardly dampen the enthusiasm of the advertisers, however. It is doubtful if anything will.

SHIBLEY, G. S. and SPIES, T. D. The Effect of Vitamin A on the Common Cold. *J.A.M.A.* 103, 26:2021 (Dec. 29), 1934.

Whither Mankind — Reviewing population trends and possibilities in the United States and other countries, the author shows that the population saturation point is placed too low and that the tropics are the goal of the white. He concludes that perhaps "the meek will inherit the earth" after all.

SMITH, W. D. World Population. *Sci. Month.* 40, 1:33 (Jan.), 1935.

Guiding Their Food Selection—School nurses who are asked to assist teachers and school administrators in suggesting better ways to manage school

lunch rooms can get some very practical points from this article.

SPALDING, M. School Lunch Survey. The Commonwealth, Mass. Department of Pub. Health 21, 3:156 (July, Aug., Sept.), 1934.

Cohesion in Nursing Education—How the State Nurses' Association, the State Board of Nurse Examiners, the State Medical Association, the State Department of Health, and the State Tuberculosis Association did some brain work in helping to prepare over 150 unemployment relief nurses to do public health work.

TEAL, H. Indiana's E.R.A. Nursing Institutes. Am. J. Nurs. 34, 12:1158 (Dec.), 1934.

Smallpox. Diagnosis and Immunity—This detailed discussion of the whole field of "pock diseases," 60 pages long, introduces a vaccinia-variola flocculation test both specific and delicate; an anteserum is described with which passive immunity may be provoked and which may be of value in sensitizing living vaccinia.

TULLOCH, W. J. The Serological Diagnosis of Smallpox and the Laboratory Investigation of Vaccinia. J. State Med. 42, 12:683 (Dec.), 1934.

Cancer Control Deficiencies—Surveying the cancer experience of a hospital in a large city, the author recommends more educational campaigns, better diagnosis, and the establishment of a division of cancer control in the State Department of Health.

WILD, W. F. A Survey of Cancer Cases in the Hospitals of Bridgeport, Conn., 1928-1932 Inclusive. Am. J. Cancer 22, 4:878 (Dec.), 1934.

Experiments in Encephalitis—Serum studies are reported that show the St. Louis type encephalitis is distinct from other forms of encephalitis and poliomyelitis.

WOOLEY, J. G. and ARMSTRONG, C. The Distribution of Immunity Against Encephalitis Virus of the St. Louis Type in the United States as Determined by the Serum Protection Test in Mice. Pub. Health Rep. 49, 50:1495 (Dec. 14), 1934.

ASSOCIATION NEWS

DR. REGINALD M. ATWATER APPOINTED EXECUTIVE SECRETARY

DR. EUGENE L. BISHOP, President of the American Public Health Association, announces the appointment of Reginald M. Atwater, M.D., Dr.P.H., as Executive Secretary of the Association. Dr. Atwater for the past 8 years has been Commissioner of Health in Cattaraugus County, N. Y., which was the first of the counties in New York State to organize on a full-time county unit basis for health.

Dr. Atwater, who is a native of Colorado, is a graduate of Colorado College and of the Harvard Medical School where he received his M.D. degree in 1918. He became a Rockefeller Foundation Fellow in Public Health and was granted the degree of Dr.P.H. by Johns Hopkins in 1921. Going to the Orient Dr. Atwater became Associate Professor of Hygiene in the Hunan-Yale College of Medicine in Changsha, China, from which post he returned to the United States in 1925 to teach in the Harvard School of Public Health.

Since 1927 Dr. Atwater has occupied his present position in Cattaraugus County where he has been in charge during the period of transition from the health demonstration to the official department of health. During his administration several active research projects have been carried out in Cattaraugus County through the coöperation of the Milbank Memorial Fund, the U. S. Public Health Service, and other agencies. Studies of tuberculosis pre-

vention and control, studies of rural water supplies, of rural health administration, and of general morbidity have been published from the Department.

Reginald M. Atwater, M.D., Dr.P.H.

The new Executive Secretary is a member of his county and the New York State Medical Societies, a Fellow of the American Medical Association, and a Fellow of the A.P.H.A. He is the author of several studies in epidemiology published in professional journals and he comes to the Association with a background of full academic training and practical experience in public health.

MISSING

GEORGE H. BIGELOW, M.D., F.A.P.H.A., formerly Commissioner of Public Health of the Commonwealth of Massachusetts, and present Director of the Massachusetts General Hospital, Boston, Mass., is missing. He may be a victim of amnesia.

Members of the Association desire that the Journal publish the following description of Dr. Bigelow.

Description: 6 ft. tall; weighs approximately 175 lbs.; has deep blue eyes; heavy shock of black hair closely cut, slightly gray at the temples. He is of rangy build. When he left his home he wore a soft brown felt hat, a black overcoat with a velvet collar, a brown suit, and tan rubber-soled shoes, and a soft white shirt. He is 44 yrs. of age. He wore a square silver wrist watch with a leather strap, and carried a brown pigskin brief case.

He disappeared December 3, 1934, having left his home in Milton, Mass., for his office in the Moseley Building at the Massachusetts General Hospital, Boston, Mass. He was to appear at 8 P.M., Tuesday night, December 4, 1934, at the Staten Island Hospital to speak, and on Wednesday at the American Society for the Control of Cancer in New York City.

The finger prints of Dr. George H. Bigelow are in the possession of the Department of

Public Safety of the Commonwealth of Massachusetts. Hospitals are requested to finger print all amnesia victims unidentified,

George H. Bigelow, M.D.

forwarding the same to Colonel Paul G. Kirk, Commissioner of Public Safety, State House, Boston, Mass.

HEALTH CONSERVATION CONTESTS FREE SURVEYS

THE American Public Health Association, in coöperation with the Chamber of Commerce of the United States, has recently announced the offer of two free public health surveys, one to a city in connection with the City Health Conservation Contest and the other to a county or district in connection with the Rural Health Conservation Contest:

The survey will consist of a careful analysis of the city's or district's public health program, its facilities and the extent to which these facilities are meeting local public health needs, and will

include a report of the appraisal thus made together with recommendations for such readjustments or changes as would seem most likely to bring about a more effective program.

The survey will be made by the field staff of the Association. Any city entered in the City Contest or any district entered in the Rural Contest (except those receiving First Award) is eligible to apply for the free survey.

If a city or district desires to be considered, the approval of the health officer should first be secured by the Public Health Committee of the local Chamber of Commerce. A formal request should then be submitted to the

Insurance Department of the Chamber of Commerce of the United States or to the American Public Health Association. Such a request may precede or accompany the fact-finding schedule. However, for cities, this application must be submitted not later than March 1, and for counties not later than March 15. At least three cogent reasons stating why the public health committee feels its city or district would benefit by such a survey *must* accompany the request.

These two free surveys will be

granted not upon the scores obtained in the 1934 competitions but upon the following main factors:

1. The need of the community for a health survey
2. The opportunity and likelihood of the community making effective use of such a survey

For further information write either the Insurance Department, Chamber of Commerce of the United States, Washington, D. C., or the Committee on Administrative Practice, American Public Health Association, New York, N. Y.

APPLICANTS FOR MEMBERSHIP

The following individuals have applied for membership in the Association. They have requested affiliation with the sections indicated.

Health Officers Section

- Laura A. Arney, 2650 N. 74 Court, Elmwood Park, Ill., Health Officer
 Frank M. Carroll, M.D., 300 Public Safety Bldg., Seattle, Wash., Commissioner of Health
 W. H. Cleveland, M.D., Tupelo, Miss., Director, Lee County Health Department
 Leslie A. Lambert, M.D., C.P.H., Court House, Flint, Mich., Genesee County Commissioner of Health
 Marion F. Loew, 32 Kenmore Place, Brooklyn, N. Y., Acting Supervisor, Tuberculosis Clinics, New York City Dept. of Health
 Harley J. Powell, M.D., Court House, Bowling Green, Ohio, Wood County Health Commissioner
 Stephen G. Wilson, M.D., Health Dept., Clinton, N. C., Health Officer

Laboratory Section

- Robert S. Cosgrove, Coöperative Clinical Laboratory, Indio, Calif., Laboratory Technician
 Wallace B. McClure, M.D., D.P.H., 28 Maryland Blvd., Toronto, Ont., Canada, Bacteriologist, Provincial Dept. of Health

Public Health Engineering Section

- Lorenz E. Ordeltcheide, B.S., Sikeston, Mo., Assistant State Director, Malaria Control, U. S. Public Health Service.
 Prof. Harry G. Payrow, B.S., Lehigh University, Bethlehem, Pa., Assistant Professor of Sanitary Engineering

Industrial Hygiene Section

- Henry F. Smyth, Jr., Ph.D., Laboratory of Hygiene, Univ. of Penna., Philadelphia, Pa., Instructor in Sanitary Chemistry

Food and Nutrition Section

- Helen S. Mitchell, Ph.D., Massachusetts State College, Amherst, Mass., Research Professor of Nutrition, Home Economics Division
 Carl S. Pederson, Ph.D., New York Agricultural Experimental Station, Geneva, N. Y., Chief in Research and Bacteriology
 Christian P. Segard, M.D., 2740 Graybar Bldg., New York, N. Y., Wisconsin Alumni Research Foundation

Child Hygiene Section

- James T. Kenney, D.D.S., State Board of Health, Jefferson City, Mo., Supervisor of Public Health Dentistry.

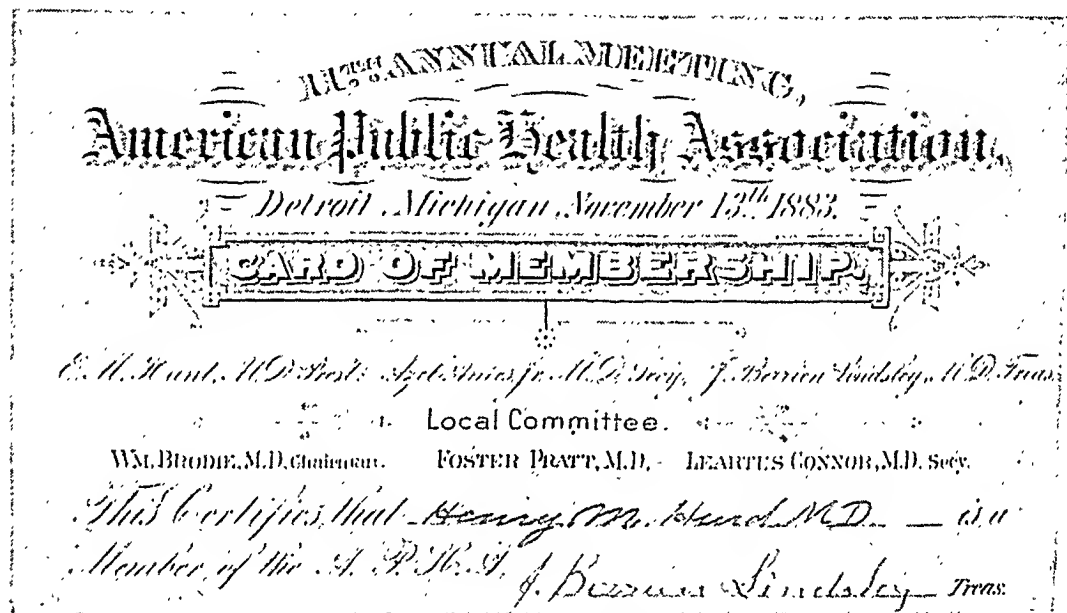

Public Health Education Section

- Gretta M. Adams, M.S., 615 Belle Ave., San Rafael, Calif., Professor of Hygiene, Dominican College
 Ramona Borree, 532 Fourth St., Haywood, Calif., Public Health and School Nursing, Alameda County Health Dept.
 Mary C. Bushard, 422 Main St., Hayward, Calif., Teacher of Home Hygiene and Public Health
 Eloise A. Hafford, 735 N. Los Robles, Pasadena, Calif., Director, Health Education, Ruth Home, El Monte, Calif.
 Walter O. Kraeft, M.S., 1107 Monroe Ave.,

A. Elizabeth Bigelow, 577 E. Main St.,

Neva R. Hackworth, R.N., Perryville, Ark.,
School Nurse

Henry Packer, M.D., 356 Oak St., New Haven,
Conn., Candidate for Dr.P.H., at Yale Univ.

John E. Ransom, Assistant Director of The Johns Hopkins Hospital, Baltimore, Md., very kindly sent to the Association an old membership card dated November 13, 1883. For the interest of the members, we are reproducing it above.

NEWS FROM THE FIELD

HEALTH EDUCATION SCHOLARSHIP AVAILABLE

A FULL tuition scholarship of \$500 is available in the field of health education at the Massachusetts Institute of Technology (Department of Biology and Public Health), Cambridge, Mass., for 1935-36. This scholarship covers the full scholastic year, beginning in September and closing in June. It is available for women only.

This scholarship will be awarded to a candidate recommended by the National Tuberculosis Association. Applicants should have basic training in mathematics, physics, chemistry, and biology. Undergraduate training in psychology and education is desirable. The awards will be based upon the nature and quality of the previous academic work of the applicant, personality qualifications for professional work in the field of public health, and need of scholarship aid. Preference will be given to candidates possessing the Bachelor's degree and having had successful teaching or administrative experience.

DU PONT OPENS NEW RESEARCH LABORATORY

E. I. DU PONT de Nemours & Company dedicated and opened on January 22 its new medical research laboratory, to be known as the Haskell Laboratory of Industrial Toxicology, the purpose of which will be to test thoroughly, from a health standpoint, all products produced by the Company before they are placed on the market.

The laboratory was planned to meet a need which has developed in this country because of the great growth of

the chemical industry as represented by du Pont. Many new products have been developed in recent years and other new products are constantly being developed, some of them through entirely new processes. A function of the laboratory will also be to study the possible effects of the new products upon the health of employees during the process of manufacture.

NEW OFFICERS ELECTED AT GENEVA MEETING

AT the meeting of the International Congress on Public Health Works held recently in Geneva, the following officers were elected:

President, M. Justin Godart

Vice-Presidents, H. E. G. DeMichelis, Sir George Buchanan, C.B., M.D., and H. E. Alfredo de Castro.

Secretary General, M. Raymond Mage.

MENTAL CLINIC FOR CHILDREN

THROUGH an endowment from the Friedsam Foundation, a new Division of Child Neurology has been created by the Neurological Institute of New York.

Dr. Bernard Sachs will be the Director of the new division, and Dr. Frederick Tilney, Director of Research of the Institute, will be Associate Director and in charge of research work. Dr. Louis Casamajor will serve as an Associate Director.

AMERICAN STUDENT HEALTH ASSOCIATION ELECTS NEW OFFICERS

AT the last annual meeting in New York City, Dr. R. W. Bradshaw, College Physician, of Oberlin College, was reelected President of the American

Student Health Association. Dr. Wade McMillan, of Miami University, was elected Vice-President, and Dr. Harold S. Diehl, member A.P.H.A., of the University of Minnesota, was elected Secretary-Treasurer.

DEATHS

HARRY F. FERGUSON, member A.P.H.A., Chief Engineer, Division of Sanitary Engineering, State Department of Public Health, Springfield, Ill., died January 16.

DR. LEWIS STEPHEN PILCHER, Editor for half a century of the *Annals of Surgery*, died December 24, 1934, at the age of 89.

PERSONALS

DR. WALTER HENRY HARTUNG, of Toledo, was appointed Director of Health of Ohio on November 28 by Governor-Elect Martin L. Davey. He is a member of the staff of St. Vincent's Hospital, Toledo.

DWIGHT S. ANDERSON, member A.P.H.A., of Woodside, N. Y., has been announced as the new Director of the Public Relations Bureau of the Medical Society of the State of New York, with offices at 2 East 103rd Street, New York.

DAVID H. MCALPINE was reelected President of the United Hospital Fund at the annual meeting of the corporation held in New York recently.

MAURICE BRODIE, M.D., member A.P.H.A., of New York, and WILLIAM H. PARK, M.D., F.A.P.H.A., of New York, were named among others as having made great contributions to medical science during 1934, as announced in *Modern Medicine*. Dr. Brodie was honored especially for his work in developing a vaccine for infantile paralysis; and Dr. Park for his development of an infantile paralysis vaccine and for his work in preventive medicine.

CONFERENCES

Mar. 27-29, Canadian Section, American Water Works Association, London, Ont., Canada.

March 31-April 7, National Negro Health Week—21st Annual Observance.

April 10-11, Montana Section of American Water Works Association, Helena, Mont.

April 11-12, Four States Section Meeting of American Water Works Association, Atlantic City, N. J.

April 24-27, National Convention, American Physical Education and its Eastern District Society, Pittsburgh, Pa.

April 29-May 3, 19th Annual Clinical Session of the American College of Physicians, Philadelphia, Pa.

May 6-10, Annual Convention of American Water Works Association, Cincinnati, Ohio.

May 24-25, Spring Meeting of New York State Sewage Works Association, Poughkeepsie, N. Y.

June 4-9, Annual Meeting, Royal Institute of Health, Harrogate, England.

June 17-19, Ninth Annual Iowa Conference on Child Development and Parent Education, Iowa City, Iowa.

June 19-22, Eighth Health Education Conference of the American Child Health Association, Iowa City, Iowa.

June 24-29, Summer Meeting of the American Association for the Advancement of Science and Associated Societies, Minneapolis, Minn.

July 15-20, Royal Sanitary Institute Health Congress, Bournemouth, England.

July 22-27, Seventh International Congress on Industrial Accidents and Diseases, Brussels, Belgium.

July 23-27, International Congress on Life Assurance Medicine, London.

Aug. 10-17, Meeting of Health Section of the World Federation of Education Associations, Oxford, England.

Number 3

Relation of the Retail Price of Milk to Production Costs^{*}

THOMAS PARRAN, JR., M.D., F.A.P.H.A.

State Health Commissioner, Albany, N. Y.

THE watersheds of our rivers have played an important part in the development of this country; but it is the milkshed of the vast stream discharging some 3 million quarts a day into the milk bottles of Greater New York which has caused a new landmark to be set up in the political economy of the state, and which has become one of the proving grounds for the joint problems of agricultural relief and industrial control. Milk has become a public utility in the sense that 7 states—and where the states have not acted, the federal government—have assumed responsibility of guaranteeing to the producers of milk a fair return, and of protecting the consumer against unfair cost. Health officials are not primarily interested in the price of milk; yet when cutthroat competition demoralizes the industry, or when low prices to producers threaten bankruptcy, or when exorbitant prices curtail the buying power of the masses, or when a milk strike shuts off a city's supply, the health officer has a

very immediate concern. In other words, in so far as the economic aspects of the milk industry have an impact upon a continuous supply of standard quality, the public health considerations loom large.

For these reasons the Legislature of New York State made the Health Commissioner an *ex-officio* member of a milk control board established in 1933. This board was given absolute authority to regulate and control every phase of the dairy industry in New York except sanitary control. The constitutionality of the law was upheld by the United States Supreme Court.

On the whole, our experience with state regulation has shown that it is of value to the producer. Dealers have operated with a narrower spread between the buying and the selling price. The farmer receives a larger percentage of the consumer's milk dollar than under previous unregulated competitive conditions. During the past 12 months New York State farmers received 23 million dollars more for their milk than in 1931 although the selling price in New York City averaged slightly over 2 cents per quart less than in 1931.

^{*} Read before the Public Health Engineering Section of the American Public Health Association at the Sixty-third Annual Meeting in Pasadena, Calif., September 3, 1934.

TABLE I

ESTIMATED COST OF PRODUCING MILK IN 1932
(Based on Warren-Misner Formula)

Item	
Grain, 30 lb. @ \$23.99 per ton ¹	\$0.36
Silage, 100 lb. @ \$6.00 per ton ²30
Hay, 60 lb. @ \$7.08 per ton ³21
Labor, 2.5 hours @ \$.20 per hour....	.50
Total feed and labor (80%).....	\$1.37
Other costs (20%) ⁴34
Total yearly cost (100%).....	\$1.71
Average net price to farmers ⁵	1.26
Loss	\$0.45
Net return per hour of labor ⁶	\$0.02

Public dissatisfaction with the price of milk in relation to what the farmer gets is a perennial topic in most cities. Few consumers understand, for example, why the farmer in New York State in July, 1934, received an average price of \$1.61 per cwt. (3.5 cents per quart) while the consumer in New York City pays 13 cents for Grade B milk and 16 cents for Grade A milk delivered at the doorstep. I shall not undertake to prove that this "spread" is justified. I shall attempt, however, to give you a statistical picture of the elements in this spread.

Let us first consider production costs. Professor Warren of Cornell University, from investigations covering 9 dairy states, has devised a formula for determining these costs. Tests in other milksheds show the formula to be accurate within 4 per cent. It is based on the fact that it requires 190 lb. of various types of feed and 2½ hours' labor to produce 100 lb. of milk. These two elements constitute 80 per cent of milk production costs. In Table I this formula is applied to feed costs in New York for the year 1932 at a 20 cents per hour labor rate. For the first 6 months of 1934 the monthly average of milk prices per cwt. was \$1.61 as compared to a production cost of \$2.16.

1. Grain is charged at \$4.00 per ton above the wholesale price for a dairy ration at Utica, N. Y., as reported in *Farm Economics*, New York State College of Agriculture.

2. Silage is charged at the approximate cost of growing and harvesting as shown by cost accounts on New York farms.

3. Hay is charged at the prevailing price on the farm, as reported in *Farm Economics*.

4. Miscellaneous costs, other than feed and labor, have been found to constitute about 20 per cent of the total cost of producing milk. In these computations, these miscellaneous costs are estimated at 25 per cent of the feed and labor costs, with labor charged at \$.20 per hour.

5. Average of the Dairymen's League net pool price and the Sheffield price, 201-210 mile freight zone, for milk testing 3.6 per cent fat.

6. The average net price for milk less all charges except for labor, divided by 2.5, the approximate hours of labor per 100 lb. of milk.

One apparent reason for the difference between the price received by the farmer and the retail price is that in New York State only about one-half of all milk produced is sold as fluid milk. Figure I shows the utilization of milk for 1931. The milk which cannot be sold as fluid milk brings a somewhat lower price as fluid cream and succes-

FIGURE I

UTILIZATION OF MILK RECEIVED AT DAIRY PLANTS IN NEW YORK STATE, 1931

Only about half the total supply for the year is used as fluid milk and less than three-fourths as fluid milk and cream. The remainder is converted into manufactured products. There are wide seasonal differences in utilization.

sively lower prices for ice cream, evaporated milk, cheese and butter. In other words, the surplus which must be sold at cheaper rates lowers the average price.

One is inclined to say, "Eliminate the surplus by reduced production or increased consumption." Unfortunately, because of the nature of the milk business a surplus of at least 25 per cent over average fluid requirements is necessary to meet unpredictable variations between supply and demand. While the farmer in New York was receiving \$1.61 per cwt. during the first half of 1934 the price he received for milk consumed as fluid milk was \$2.40, while that paid for milk which went into butter and cheese averaged less than \$1.00.

These prices which I quote are at the country milk plant, 200 miles from New York City. More or less actually is paid depending upon whether the milk is closer to or further from New York City.

The elements which enter into the dealer's spread are summarized for 19 New York City dealers for August,

1933, for fluid milk and fluid cream (see Table II). At that time the retail price of home-delivered milk was 12 cents and 15 cents, yet attention is called to the fact that the average sale by the dealer, wholesale and retail, amounted to only \$.086. Prices of milk at stores were 1 and 2 cents less than the home-delivered price. The actual utilization of milk by classes is shown in a later table.

Attention is called also to the great variation in the efficiency of operation of these 19 dealers. Only 5 of them made a profit for that month. One or two of the largest made relatively large profits, while a considerable percentage were losing money. This factor introduces a most baffling problem in attempting to fix milk prices to producers and to consumers. Obviously the state cannot guarantee a profit to the least efficient element in the industry. Should prices be set which will drive out of business one-quarter, one-half, or nearly all of the milk dealers? To do this would tend to create a monopoly, and with the present uncertainty as to the nature and extent of permanent state

TABLE II

SUMMARY OF SALES, COSTS AND PROFITS, 19 NEW YORK CITY DEALERS, AUGUST, 1933

* These margins were computed as follows: The quoted Class I or Basic Prices were adjusted to a uniform basis. The quoted prices for each market were adjusted so as to apply to milk of the average fat content sold in each city. The margins given are the result of subtracting the adjusted Class I or Basic Prices from the quoted retail prices for each market as reported by the U. S. Department of Agriculture. From these margins must come the cost of city processing and distribution, and the distributors' profits.

and federal control this seems contrary to the public interest. In other words, unless rigorous control is to be exercised permanently, or unless cities themselves are to operate milk distribution systems or give limited franchises to one or two companies, it does not seem reasonable to destroy a large number of distributors even though admittedly there are too many for efficient operation. There is an even more practical consideration. When faced with losses milk dealers, in spite of rigorous laws, will seek to evade the required payments to farmers; or, if a dealer does go into bankruptcy, a large group of farmers stand to lose several months' milk payments and often are left with no market outlet.

The problem of the dealer's spread becomes somewhat simplified when we consider the actual operating costs for a typical month, as shown in Table II. How justifiable each of these costs may be furnishes ground for debate. Let us consider two items. There are too many distributors for efficient operation; there are also too many country plants.

Country plant costs approximate $\frac{1}{2}$ cent per quart. One-half the number would operate as efficiently, but in a highly competitive business how can the state compel combinations of plants short of actual ownership?

Delivery and selling costs amount to nearly $2\frac{1}{2}$ cents per quart. If home deliveries alone were considered this cost would be nearly doubled. It is obvious that unified selling and delivery in place of the present multiplicity of plants, trucks and wagons would reduce these costs materially if equal efficiency of operation could be assumed. It would be of interest if some city in the country were to experiment with municipal operation of the milk distribution system. Bearing in mind natural variations in costs between different cities because of obvious factors, some yardstick as to relative performance would be had. In connection with variations in costs between different cities, data collected by a legislative commission in New York will be of interest and are shown in Table III. These margins were adjusted to make

the comparison as accurate as possible.* Natural variations in spread depend upon many local factors which cannot be discussed in the limits of this paper.

cent although at present the decline has halted and seems to be started on an upward trend again. This reduced consumption, coupled with a slightly in-

* Includes small amount of certified and other special milk.

In Table IV the gross spread of 19 New York State dealers for August, 1933, is analyzed. From this it is seen that, from the total volume of milk equivalent, 50 per cent was sold as Grade B fluid milk, 12 per cent as Grade A, 22 per cent as cream, and 16 per cent in various by-products.

In recent years a new factor has entered into the costs of most kinds of business. This is the lack of capacity operation. Milk consumption in New York City has dropped about 15 per

cent although at present the decline has halted and seems to be started on an upward trend again. This reduced consumption, coupled with a slightly in-

creased production of milk, is the primary factor which brought about the collapse in milk prices and the resultant state control. Because present consumption of milk throughout the state is considerably less than is needed for normal human nutrition, to meet this problem New York has pioneered in state action to increase consumption through advertising. The cost is borne jointly by producer and dealer. If this venture is attended with the same success as experienced in advertising other food commodities, both public and industrial health will be promoted thereby.

* For full discussion see Report of the Joint Legislative Committee to Investigate Milk Industry, page 187.

The milk industry, like others, has been criticised for over-capitalization, for seeking to pay dividends on "watered stock," and similar practices common to American business generally.

The data I have given above do not relate to return on capital but solely to operating costs. In 1931, 28 of the larger distributors in New York City valued good will at 7.4 per cent of total assets. The valuations of lands, buildings, and equipment probably represented the previous higher level of prices. Studies made by the New York Milk Control Board in August, 1933, sought to eliminate from reported costs and capital investment every unnecessary or "padded" item. These adjustments in cost and net worth included holding company charges, excessive salaries of officers, idle property, good will, and increase in value of fixed assets. This reduction both in reported costs and investment increases the apparent rate of return on the dealer's net worth from $1/8$ per cent to $3\frac{1}{3}$ per cent per year. However, this maximum apparent saving in costs would amount only to $1/10$ cent per quart of milk. In other words, excessive salaries and over-capitalization in themselves do not contribute materially to the price of a quart of milk. If substantial reductions in the costs of milk to the public are to be made, they must be accomplished through more efficient operations or the elimination of costly services.

This is a brief sketch of milk costs and control measures up to date. What of the future? What are the objectives? In my opinion state control

must provide the consuming public with an adequate and continuous supply of safe and wholesome milk at a price which represents a just return and no more to producers and distributors for their labor and investment. Costs cannot be guaranteed either to the inefficient producer or distributor. Milk has become a public utility in effect if not in name in New York and in many other milksheds of the country. In other public utilities we have seen some measure of public ownership and operation following earlier attempts at regulation. Shall we see a similar venture in the milk industry? Some thoughtful students of the problem see no way of reducing materially the present spread between the retail price of milk and the price received by the farmer unless major reforms are made in the industry, or unless the state or municipalities undertake public operation. The necessary major reforms to increase efficiency are scarcely possible unless in each milkshed a practical monopoly is exercised either by farmers' coöperatives, by the distributing companies, or by both.

If there should be a real shortage of milk as prophesied in bulletins following the recent drought, competitive conditions of previous years again may prevail. So long as production continues greatly in excess of fluid consumption, public regulation of prices to farmers probably will be continued. If production costs increase and consumer resistance to higher prices tends to reduce consumption, there may be public demand for major reforms in milk distribution or municipal operation.

The Cause of Breast Cancer*

EMIL BOGEN, M.D.

Olive View Sanatorium, Olive View, Calif.

THE prominent location, characteristic clinical course and high fatality rate of cancer of the breast make its official mortality returns a particularly reliable index to its actual occurrence.¹ Examination of the data for different times and places reveals variations in its incidence deserving analysis and interpretation that may well be withheld from forms of cancer offering greater difficulty in recognition.²

The number of deaths from cancer of the breast in any particular time and place tells us little regarding its relative importance unless this is expressed in terms of the number of persons exposed to such a possibility. The rate for the entire population is usually the most readily ascertainable figure. This may be, however, quite misleading, if variations in the composition of the population affecting this rate are not recognized.³

Since nearly 99 per cent of all cancers of the breast occur in women,⁴ the rate for the entire population may be expected to be low in regions where males predominate, as in Nevada with 14 males to each 10 females, and high in places where there is an excess of females, as the District of Columbia with only 9 males to each 10 females.⁵ This source of error is eliminated in tables in which the deaths are expressed in terms of the number of females liv-

ing, but for most large populations it is of little importance.

The age distribution of the population constitutes a much greater source of variations and misconceptions. Cancer of the breast, as most other forms of cancer, is almost unknown in childhood and youth, and extremely rare in young adults, but its incidence increases rapidly during middle life and continues to rise up to extreme old age. The greatly higher death rate from breast cancer in older people is shown in practically all statistics that have been examined (Table I).

TABLE I
AGE AND BREAST CANCER,
U. S. REGISTRATION STATES, 1930

The actual number of deaths from breast cancer at the different ages, accordingly, varies with the age composition of the population concerned. Not only will there be a lower incidence of breast cancer in places with relatively few old people than in places where there are more aged inhabitants, but the age at which the majority of

* Read before the Vital Statistics Section of the American Public Health Association at the Sixty-third Annual Meeting in Pasadena, Calif., September 3, 1934.

the cancers actually appear will be correspondingly lower. Thus, in New Mexico, where less than 18 per cent of the population is over 45 years of age, only 61 per cent of the deaths from breast cancer occur after this age; while in New Hampshire, where more than 30 per cent of the population is over 45 years of age, more than 87 per cent of the breast cancer deaths occur in this age group.

A similar change in the age distribution of the persons dying with breast cancer as a result of the aging of the entire population may be seen in the returns for the U. S. Registration States of 1910 during the past two decades (Table II).

TABLE II

BREAST CANCER DEATHS IN THE U. S. REGISTRATION STATES OF 1910

Population	1911	1920	1930
Breast Cancer....	3,610	4,900	7,409
Rate All Ages*..	7.5	8.8	11.2
Rate Age 15-44..	2.9	3.1	3.6
Rate Age 45-64..	22.1	25.6	34.0
Rate Age 65-....	49.8	55.0	61.6
% Population over 45	20.9	24.0	25.6
% Breast Cancer over 45.....	80.6	82.7	84.4

* All rates, per 100,000 aggregate population.

Most, but not all of the increase in the proportion of breast cancer deaths occurring above 45 years of age in recent years may be ascribed to this change in the age distribution of the entire population. A small but significant lowering of the mortality rates

from this cause at the younger ages, however, and a definite increase in the older age groups, may be seen (Table III). The prolongation of life through palliative surgical and radiation therapy, even in incurable cancer of the breast, may be, at least in part, responsible for this change.⁶ This is supported by the fact that the average age of breast cancer cases reported in hospital statistics and in surgical reports is distinctly lower than that found in mortality reports.⁷

The crude mortality rate from breast cancer in the U. S. Registration Areas, as in most other countries, has been steadily rising during the past 30 years. By far the greater part of this change is obviously due to the change in the age distribution of the population. Even in the standardized or the age specific rates, however, an upward trend may be observed (Table II).

With the improvement in diagnostic methods, and the wider use of medical services, more cancers of inaccessible sites are being recognized, with consequent increase in the total number of cancer deaths reported.⁸ Accessible tumors such as those of the breast may be expected to share but little in this increased recognition. Accordingly, the fact that there has been no decrease in the proportion of breast cancers to the

FIGURE I—BREAST CANCER IN THE UNITED STATES, 1900-1930

total number of cancers also indicates that there has been an increase in the real prevalence of this condition (Table IV and Figure I).

Since these mortality figures do not include the increasing numbers of persons who have been successfully operated upon for cancer of the breast in recent years,⁹ there seems little doubt that the actual incidence of breast cancer is increasing, at least in this country and Great Britain.

The frequency of breast cancer in different countries varies widely.¹⁰ The data need to be adjusted for the large variations in the age distribution in different countries, but this does not suffice to remove the marked discrepancies noted. Deficiencies in the completeness of death registration and in the accuracy of diagnosis in different countries, it would seem, should lead to an apparent lowering of the absolute incidence of breast cancer, but to an

apparent increase in the proportion which it constitutes of all cancers. The close parallelism between these two types of data, however, indicates that the differences observed between countries is not generally due to variations in the age and sex distribution, or in the adequacy of death registration (Table V).

The rarity of all cancers in primitive peoples has been seriously questioned,¹¹ but as to its relatively infrequent localization in the female breast there appears little doubt. Available information from Japan and India, and from Chile and Uruguay, reveals breast cancer in these countries extremely seldom as compared to the European countries, while the English speaking countries report much higher figures.¹²

Different states in the United States show similar differences, which may not be entirely explained away by variations in the age and sex distribution of the population, or by differences in the adequacy of registration and diagnosis, although these may play a part. Thus, in 1920 the breast cancers in Massachusetts, with an adjusted mortality rate of 11.2 per 100,000 population, constituted 11.3 per cent of all cancers in that state, while in Mississippi, with an adjusted mor-

Chile	1.2	2.0	39.8	37.0

tality rate of 3.4 per 100,000 they constituted only 6.8 per cent of all cancers.¹³

In general, breast cancer mortality rates have been higher in urban than in rural districts, in northern than in southern states, and in whites than in negroes. Although a large part of the

apparent differences in the crude rates disappears when they are adjusted for age distribution, the general relations remain, and the proportion of breast cancers to all cancers shows the same relations (Table VI).

It has been repeatedly noted in recent years that cancer of the breast is relatively much more frequent in single than in married women.¹⁴ It appears also to be true that among the married women cancer of the breast is more often encountered among the nullipara than among those who have borne children, and there are indications that it is even less frequent among those who have had a large number of children.¹⁵

These last observations may be readily harmonized with the foregoing mortality statistics, and go far to clarify the differences that are observed. If childbearing and lactation tends to prevent cancer of the breast, it may be readily expected that the incidence of cancer of the breast in recent years would rise in most places with a falling birth rate, and that the countries with higher birth rates, like Japan, or the southern and rural districts in the United States, or the negroes and other population groups having a higher birth rate, would still have a low incidence of cancer of the breast.

If the states are arranged in the order of their breast cancer mortality rates for the female population over the age of 45 only, thus avoiding discrepancies due to age and sex differences, there is found a very high inverse correlation with that obtained by taking them in the order of their birth rate for the female population between the ages 15 and 45. In other words, generally speaking, states with a high breast cancer rate have a low birth rate, and *vice versa*.

Logically, of course, we may expect that the birth rate of 30 years or so prior, when the women now developing

BIRTH RATE IN THE
UNITED STATES

cancer of the breast were in their child-bearing age, would better reflect the influences bearing on them than that today. Unfortunately, the U. S. Registration Area for Births is only 18 years old, and has only recently included all of the states. The census for 1900,¹⁶ however, included an attempt at an approximation of the birth rate in the various states at that time, and this may be taken, for want of better, for comparison. It may be seen that although the actual birth rate has decreased markedly in practically all parts of the country, the relative order of the different states shows little change not accounted for by differences in the age and sex composition of the people. Accordingly we find again that the states with the high breast cancer rate in 1930 generally showed a low birth rate in 1900, and the states with the high birth rate in 1900 are found to have a low breast cancer rate in 1930 (Table VI and Figure II).

Available data for the different countries of the world agree with this finding (Table V). Arranging the various countries in the order of increasing birth rate in 1900, or before the war,

gives almost the same list as that in the order of increasing mortality rate from cancer of the breast, or the ratio of breast cancer to total cancers. A superficial inquiry into the different countries involved also emphasizes the fact that cancer of the breast is more prevalent where early weaning of the infant is the rule, and is less often met with where breast feeding is common and prolonged.

Clinical investigation of large groups of women suffering from cancer of the breast confirms and amplifies these observations.¹⁷ Not only is cancer of the breast found with disproportionate frequency in single women and in nullipara, but it is also more prevalent among women who have had miscarriages or stillbirths or for some other reason, although pregnant, have failed to nurse their young. Particularly suggestive are the reports of cases where cancer has developed in an unused breast, and not in the contralateral lactating breast.

These are objective facts gleaned from an impersonal survey of official records and clinical data by a number of different workers, and confirmed by a series of case records personally examined for the present study. They indicate quite definitely that the retention of milk and other secretions in the breast due to non-lactation may be a potent factor in the production of many, if not all, cases of carcinoma of the mammary gland, and that the removal of such substances by suckling exerts a definite prophylactic effect against the development of such tumors.

Animal experimentation sheds further light on this phenomenon. White mice that have had their young removed at birth, so that they cannot suckle them, develop mammary carcinoma quite similar to the breast cancers in women. That this is due to local retention of secretions and not to a general endo-

crine disturbance is shown by the fact that white mice that have had their breasts occluded on one side only by ligature develop cancer on that side, and not on the other. These findings, first reported by Bagg nearly a decade ago,¹⁸ have been amply confirmed in our experience at Olive View (Table VII).

TABLE VII

EXPERIMENTAL INDUCTION OF MAMMARY CARCINOMA IN MICE

Olive View, Calif., 1932-1934

Procedure	Total Number of Mice	Average Number of Litters	Average Survival Period, Months	Number Developing Breast Cancer	Per Cent Developing Cancer
Young removed at birth.....	18	7	18	10	55
Nipples on left side ligated, suckling with right side	18	4	15	6	33
Normal breeding controls	18	5	18	0	0

Recent investigations into the carcinogenic actions of tars and related substances have shown that a reduced derivative of cholesterol is capable of producing cancer just as effectively as are some of the coal tar and other phenanthrene compounds.¹⁹ Cholesterol is present in the ducts of the non-lactating female breast of the virgin, as well as in the secretions of the lactating breast,²⁰ and in the absence of the normal drainage that comes with lactation, it may undergo the reductions that would lead to the development of carcinogenic properties. Childbirth and lactation constitute, accordingly, a natural protection against this endogenous carcinogenic agent.

SUMMARY

Analysis of available vital statistics shows that cancer of the breast is strikingly associated with a low birth rate. Clinical investigation confirms

this finding and indicates that it is more particularly related to lack of drainage of the mammary glands. Animal experimentation shows that this is due, not to endocrine derangement subsequent to the lack of suckling, but simply to the local retention of secretions in the non-lactating breast. Recent chemical investigations have revealed the existence of chemical substances in the normal breast secretions which may, after many years of retention, exert carcinogenic effects similar to those well known to result from the exogenous application of certain coal tars. The results of the clinical, biological and chemical investigations concur with those of the analysis of the vital statistics in emphasizing the etiological rôle of retained mammary secretions in the development of cancer of the breast.

Efficacy of Typhoid Prophylaxis in the United States Navy*

S. S. COOK, M.D., DR.P.H.

Lieutenant Commander, Medical Corps, U. S. Navy, In Charge, Division of Preventive Medicine, Bureau of Medicine and Surgery, Navy Department, Washington, D. C.

TYPHOID fever was for many years a serious problem in the United States Navy and epidemics were frequent aboard ship and on shore stations. That much time and thought was expended in efforts to solve this problem is evidenced by frequent references in the reports of medical officers of the late years of the 19th century and in the early years of the 20th century.

For this study the 44 year period 1890-1933 has been chosen. The initiation of compulsory typhoid prophylaxis in 1912 serves as the dividing line separating the 44 years into 2 periods of 22 years each. There are given the annual prevalence, deaths, case fatality, and geographical distribution during the period when vaccine was not administered and for comparison during the years when vaccine was administered, also the effects of inoculations with relation to severe reactions and deaths and, for a portion of the period, an account of the incidence of typhoid fever in individuals previously inoculated.

Reports of encouraging results following the use of antityphoid prophylaxis prompted naval authorities early in 1910 to make typhoid vaccine available to those who wished to avail themselves

of it. In 1911 it was decided to require inoculation of all naval personnel, and this was done in General Order No. 133, dated December 1, 1911. This order reads:

1. As soon as practicable after the receipt of this order, typhoid prophylactic will be administered to all officers and enlisted men of the Navy and Marine Corps, under the age of 45 years, who have not already received it or who have not already had a well defined case of typhoid fever. Officers and enlisted men on leave, or on duty where no medical officer is available, will receive the typhoid prophylactic upon their arrival at the first station where this measure is practicable.

2. Typhoid prophylactic will be administered to all recruits under 45 years of age immediately upon their arrival at a training station, receiving ship, or marine recruit depot. This applies to all men reenlisting who have not received the prophylactic treatment within 2 years previously or had a well defined case of typhoid fever; in case of doubt the prophylactic will be administered. Every applicant for enlistment in the Navy or Marine Corps will be informed that he must submit to typhoid prophylaxis, and unless he agrees to acquiesce in this procedure he will not be considered for enlistment.

3. Typhoid prophylaxis must be regarded as a supplemental safeguard, and under no circumstances will the usual sanitary precautions be modified or set aside.

4. The antityphoid serum should be obtained from the Bureau of Medicine and Surgery by telegraphic or written request.

This order was promulgated to the service and immediate steps were taken to comply with its provisions. Inocula-

tions were begun early in 1912, and by the end of that year practically every person in the Navy to whom the order applied had received 3 injections of typhoid vaccine.

While there have been some minor modifications of the instructions it has

not been found necessary to alter materially the original method. At present, two courses of 3 injections each are generally regarded as adequate protection. The vaccine has been obtained from the Army Medical School.

In Table I are shown the admissions

and deaths from typhoid and paratyphoid fevers among officers and enlisted men of the United States Navy for the 44 year period 1890-1933. There were 3,409 admissions and 296 deaths with a case fatality of 8.68 per cent. In the 22 year period 1890-1911, in which typhoid vaccine was not administered, there were 2,837 admissions and 252 deaths and in the 22 years 1912-1933 there were 572 admissions and 44 deaths. The case fatality rate for 1890-1911 was 8.88 per cent, and for 1912-1933 it was 7.69 per cent.

There is a striking difference in admission rates and death rates in the 2 periods. From 1890 to 1911, in only 1 year was the admission rate lower than 300 per 100,000. In 6 of the 22 years the rate exceeded 500, and in 1899 and 1900 the rates were 643 and 736 respectively. There was an abrupt drop from a rate of 361 in 1911 to 92 in 1912. Antityphoid inoculation of the entire Navy was not completed until the

end of 1912 which may account for the higher rate in 1912 than for succeeding years. Except for the rate of 92 in 1912 the admission rate in the period 1912-1933 has never exceeded 35 per 100,000. In the 5 years 1913-1917, immediately following the inauguration of compulsory antityphoid prophylaxis, the rate fluctuated between 30 and 35. In the 16 year period 1918-1933 there was only 1 year when the rate exceeded 20, and in 5 of these years the rate was less than 10 per 100,000.

The decline in death rates which occurred after the introduction of compulsory antityphoid inoculation is remarkable. In the 22 years 1890-1911 there were only three occasions when the death rate was less than 20 per 100,000. In 8 of these years the rate exceeded 50, and in 15 of the 21 years it exceeded 30. In the 22 year period 1912-1933 the death rate per 100,000 was less than 3 in each year except 1912, 1913, and 1920, when it was 3, 6,

1926	3	2.64	0	0
1927	9	7.81	1	0.87
1928	9	7.76	1	0.86
1929	7	5.96	1	0.85
1930	11	9.37	1	0.85
1931	16	14.19	2	1.77
1932	12	10.84	3	2.71
1933	6	5.55	2	1.85

and 5 respectively. In the 19 years when the death rate was less than 3 there were no deaths in 5 of the years, and in 5 others the rate was less than 1. The death rate declined abruptly from 24 in 1911 to 3 in 1912.

Prior to 1913, typhoid fever and paratyphoid fevers were not separated in morbidity reports. In Tables II and III admissions and deaths for typhoid fever and for paratyphoid fevers from 1913 to 1933 are shown.

It may be seen in Table II that typhoid fever caused 378 admissions and 39 deaths in the 21 year period 1913-1933. This gives an average of about 18 cases and 2 deaths per year in a population of approximately 142,000. If the war years of 1917 and 1918 are excluded a better idea of the usual prevalence is obtained. Thus, in 19 of the years since antityphoid inoculation has been in use there has been an average of about 13 cases and 1 death in a population of approximately 118,000.

In Table III are shown admissions and deaths, by years, for paratyphoid fevers for the period 1913-1933. There were 137 admissions and 3 deaths. From 1912 to 1917 straight typhoid vaccine was used. From October, 1917, until the summer of 1924 a triple vaccine, which contained typhoid, paratyphoid A and paratyphoid B organisms, was given. Since 1924 straight typhoid vaccine has been used. There does not appear to have been a marked decrease in the prevalence of paratyphoid fevers as a result of the use of the triple vaccine. The numbers of cases are too small to warrant definite statements one way or the other.

In Table IV are shown annual death rates per 100,000 strength, United States Navy, and per 100,000 population, Registration Area of the United States, 1900-1929.

During the first 5 years of this period Navy death rates were consistently higher than those of the Registration

* The death rates for the Registration Area of the United States for the period 1900-1919 are those shown in Mortality Statistics under Title No. 1, *International Nomenclature* for typhoid fever and paratyphoid fevers and for 1920-1929 under Title No. 1a for typhoid fever and No. 1b for paratyphoid fevers.

Area. Beginning with 1905 and continuing through 1911, Navy rates paralleled quite closely those of the Registration Area. From 1912 on there is no similarity. The death rate in the Navy dropped from 24 in 1911 to 3 in 1912, while in the Registration Area it dropped from 21 to 16. The decline in the Navy was precipitous whereas in the Registration Area the decline, which had

been in progress since 1900, continued in an orderly but gradual fashion. So far as can be determined the only change which was made in the Navy in 1912 that was not made in the Registration Area was the inauguration of antityphoid inoculation. Such improvements as were effected in sanitation including water purification doubtless affected the Navy as well as the civilian population. If it were found that the principal sources of infection for the Navy were localities where notable sanitary improvements had been made in 1912 this factor would of necessity require consideration.

The geographic distribution of typhoid fever in the Navy, 1900-1912, is here given in sufficient detail to substantiate the statement that the disease was prevalent in the Navy in a number of localities both in the United States and elsewhere.

GEOGRAPHIC DISTRIBUTION

Abstracts are given from official records in chronological order:

1900—Island of Guam, 18 cases; a ship, Atlantic Fleet, 4 cases; Gavite, P. I., 26 cases; a ship, Asiatic Fleet, 11 cases.

1901—Asiatic Station, 19 cases; a ship, Atlantic Fleet, 9 cases.

1902—Training Station, San Francisco, 7 cases.

1903—San Juan, P. R., 7 cases in Atlantic Fleet; Naval Academy, Annapolis, Md., 7 cases; Navy Yard, Norfolk, Va., 6 cases; Navy Yard, Philadelphia, Pa., 9 cases; a ship, Atlantic Fleet, 7 cases.

1904—Portsmouth, N. H., 22 cases; Receiving Ship (U. S. S. *Franklin*), Norfolk, Va., 11 cases; a ship, Atlantic Fleet, 13 cases.

1905—Training Station, Newport, R. I., 12 cases; Receiving Ship (U. S. S. *Franklin*), Norfolk, Va., 16 cases; Naval Academy, Annapolis, Md., 11 cases; Asiatic Fleet, 16 cases.

1906—A ship, Atlantic Fleet, 44 cases; Naval Academy, Annapolis, Md., 9 cases; Training Station, Newport, R. I., 16 cases; Asiatic Fleet, 8 cases; Foreign Stations, 13 cases.

1907—A ship, Atlantic Fleet, 8 cases; Foreign Stations, 11 cases; Asiatic Fleet, 9 cases.

1908—Norfolk, Va., 31 cases; Las Animas, Colo., 28 cases.

1909—Atlantic Fleet, 98 cases; Chelsea, Mass., 24 cases.

1910—Receiving Ship (U. S. S. *Franklin*), Norfolk, Va., 17 cases; a ship, Atlantic Fleet, 12 cases; Foreign Stations, 5 cases.

1911—Marines, Guantanamo Bay, Cuba, 11 cases; Foreign Stations, 16 cases.

1912—Fourteen ships and 8 shore stations reported 1 case each.

TYPHOID PROPHYLAXIS

Data are available for the 9 year period 1925–1933 with regard to the number of injections given in these years and the reactions and deaths resulting therefrom. These are shown in Table V. There were 291,796 complete

injections caused 8,773 moderately severe reactions, in 2,125 instances the reaction was of sufficient severity to require admission to the sick list, and there was 1 death. There was 1 moderately severe reaction to 102 injections and 1 admission to the sick list to 421 injections. In other words, some type of reaction followed slightly more than 1 per cent of the injections.

During the 10 year period 1924–1933 there were 81 cases of typhoid fever, and of this number 73 had records of previous inoculations with typhoid vaccine. Of the remaining 8, 1 had received 1 injection; 4 had not been inoculated; and for 3 there is no record.

TABLE V

TYPHOID PROPHYLAXIS, UNITED STATES NAVY, 1925–1933

	First-Course Inoculations	Second-Course Inoculations	Total
Number administered	620,135	275,545	895,680
Moderately severe reactions	7,751	1,022	8,773
Per cent	1.25	0.37	0.98
Reactions requiring admission to sick list	1,825	300	2,125
Per cent	0.29	0.11	0.24

courses of 3 inoculations each, January 1, 1925, to December 31, 1933.

Deaths resulted from antityphoid inoculations as follows: 1918, 2; 1923, 1; and 1926, 1.

During the 9 year period 895,680 inoculations were given. These inocu-

The time interval between inoculation and admission with typhoid fever is shown in Table VI.

It may be seen that 5 individuals developed typhoid fever within 6 months of the completion of inoculation, and slightly more than one-half the total

TABLE VI

TYPHOID FEVER IN PERSONS PREVIOUSLY INOCULATED, UNITED STATES NAVY, 1924–1933
INTERVAL BETWEEN INOCULATION AND ADMISSION

Year	0–6 Mos.	6 Mos.–1 Yr.	1–2 Yrs.	2–3 Yrs.	3–4 Yrs.	4 Yrs. +	Total
1924	2	1	1	..	4
1925	1	..	2	..	1	4
1926	1	..	1	2
1927	2	2	1	1	2	8
1928	1	1	3	2	1	..	8
1929	1	2	..	1	1	..	5
1930	1	3	1	3	2	1	11

1932	1	2	3	3	1	10
1933	1	1	3	5
Total	5	12	20	19	10	7	73

cases occurred between 1 and 3 years after receiving 3 injections of typhoid vaccine. It is noted that there was an increase in the numbers of cases in 1930, 1931, and 1932, as compared to the years immediately preceding. The 11 cases in 1930 were reported from widely separated places under varying conditions of exposure. Of the 16 cases in 1931, 12 were reported in Marines in Nicaragua. An earthquake in March, 1931, caused extensive damage to the water works in Managua and for several months thereafter the water was grossly polluted. The water supply of the Marine Camp was chlorinated but there were numerous opportunities for exposure in the city. In 1932 there were 10 cases and of these 8 occurred in China.

SUMMARY

Typhoid prophylaxis was instituted in the Navy in 1912 and has been consistently practised since. Specific

prophylaxis has consisted of the administration of typhoid vaccine to all persons in the Naval service.

Coincident with the prophylaxis a marked reduction in the incidence of typhoid fever occurred. This reduction is believed to have been due in large measure to the immunization of the personnel. The incidence of typhoid fever has gradually declined in the Registration Area of the United States. Since 1900 this decline has been more gradual than that observed in the Navy and has at no time shown the marked drop comparable to that in the Navy in 1912.

In the 9 year period 1925-1933, 895,680 injections of typhoid vaccine were given. As a result of these injections there were 1 death and 10,898 reactions. Some type of reaction followed slightly more than 1 per cent of the injections.

In the 10 year period 1924-1933 there were 73 cases of typhoid fever among persons who had received 3 or more injections of typhoid vaccine.

Less Lead Permitted on Apples and Pears

IN a notice addressed to both consumers and producers of apples and pears, Secretary of Agriculture Wallace announced a further restriction in the quantity of lead residue permitted on these fruits in interstate commerce. The tolerance specified for the crops of 1935 is 0.018 grain of lead to a pound of fruit.

The reduction was made despite requests from some quarters that the restrictions be relaxed, the Secretary adding that "expectation of continued progress downward is fully justified" and "relaxation in the lead restriction would be wholly incompatible with public safety." U. S. Dept. of Agriculture, *Press Release*, Jan. 25, 1935.

Efficacy of Typhoid Prophylaxis in the United States Army*

MAJOR GENERAL ROBERT U. PATTERSON

The Surgeon General of the U. S. Army, Washington, D. C.

BEFORE discussing the efficacy of typhoid prophylaxis, or so-called typhoid vaccination, it is desirable to refer to the history of the procedure and then trace its development up to the present time.

As early as 1886, Fränkel and Simmonds¹ found that several small non-lethal doses of typhoid bacilli would protect rabbits against subsequent fatal doses. In the same year, Beumer and Peiper² immunized mice with potato cultures of typhoid bacilli, and by using small but increasing doses they were able to give definite protection subsequently against what ordinarily would have been fatal doses. They suggested the use of sterilized or killed cultures to be used for the immunization of men, but made no investigations or experiments themselves. Chantemesse and Widal,³ in 1888 Sanarelli, and others reported work on animals of similar character, but as practically nothing was then known of the toxin of the typhoid bacillus or of the nature of typhoid immunity, little or nothing came of their work. In 1892, Brieger, Kitasato, and Wassermann⁴ demonstrated that it was unnecessary to use living bacilli, since killed cultures were

part of the body of the bacillus. Both filtrates, which had been used to some extent up to that time, were effective only in so far as they contained particles of bacterial cells.

All of the earlier work on animals was incomplete and unsafe as a guide in the immunization of man, as at that time there was no way of detecting changes in the blood serum after inoculation and, consequently, no way of knowing that protection had been conferred. It was not until 1894 and 1895 that Pfeiffer,⁵ working with Wassermann, Kolle, and Issaeff, discovered the nature of the immunity in cholera and typhoid and at the same time elaborated a method of measuring its quantity. They recognized that the character of the immunity and its degree depended upon the presence of bacteriolytic immune bodies in the blood serum, and the test formulated at that time has since become classic under the name of the "Pfeiffer phenomenon." The test is made by inoculating a series of guinea pigs intraperitoneally with fatal doses of cholera or typhoid mixed with diminishing quantities of immune sera followed by examination of the peritoneal exudate for signs of degeneration in the bacteria. If they are dissolved and the pigs live, the phenomenon is present; if the bacteria are not attacked the pigs die and the test is negative. Until the discovery of agglutinins and, later, of opsonins, the entire fabric of

proof of the efficacy of immunization depended upon the demonstration of bacteriolytic amboceptors in the blood serum. The results obtained by this test proved conclusively in both animals and man the possibility of producing a high degree of immunity against typhoid by the use of killed cultures.

The first actual immunization of men for the purpose of protecting them against typhoid was made by Pfeiffer and Kolle⁶ in 1896. They immunized two men and investigated the specific changes in the blood serum thoroughly and exhaustively. They showed that not only were agglutinins produced, but what is more important, the bacteriolytic power of the blood was also raised in the same way as during an attack of typhoid. So far as was known then, we had the same antibodies produced as the result of inoculation as were produced during an actual attack of the disease. It was therefore not unreasonable to expect that the immunity conferred by prophylactic inoculation would last for a considerable period.

Sir A. E. Wright,⁷ who in 1896 was connected with the Medical Corps of the British Army, had injected killed cultures of typhoid bacilli into two men a few weeks before Pfeiffer and Kolle, but the inoculations were apparently made in the course of investigation on the coagulability of the blood, since he reported no studies of the specific changes in the blood. In the next year (1897),⁸ however, he published the results of antityphoid inoculations upon 18 men and became convinced by this experience that the method was practicable and that it gave sufficient protection to make it worthy of adoption in the Army.

In 1898, Wright introduced typhoid prophylactic inoculation into the British Army in India, with results which were on the whole very good and encouraging. Wright used broth cultures which had been incubated for 3 weeks and then

killed by heating to 60° C. for 1 hour. The size of the dose used was the quantity required to kill a small guinea pig.

During the Boer War, Wright recommended that the troops be inoculated. Four hundred thousand doses were furnished, but it is not known how many received the vaccine. Statistical reports were poor, the opinions of organization surgeons differed, and although Wright was convinced from the data he had collected that both morbidity and mortality were reduced, the procedure was not popular.

Sir William Leishman⁹ says relative to the Boer War experience:

The methods then employed in the preparation of the vaccine may have resulted in considerable variations in its vaccinating efficiency. Some men may have received but slight and transient immunity, while others were protected in as high a degree as the system was capable of.

No doubt overheating the vaccine was one of the main factors in obtaining lack of uniformity of results.

Following the Boer War, the next extensive use of typhoid vaccine was in the German Colonial Army in South Africa from 1904 to 1907. In 1904 the Germans had 226 cases of typhoid among their troops and, upon the advice of Professor R. Koch, prophylactic vaccination was employed with the result that the number of cases fell to 43 during 1907.

Kuhn¹⁰ has reported the results of this work which may be summed up as follows:

Sixteen thousand four hundred and ninety-six men were sent to the Colonial Army. A call for volunteers resulted in 7,287 men being vaccinated. Large doses of vaccine were given and reactions were severe. One thousand two hundred twenty-seven cases of typhoid developed; among the unvaccinated the percentage of cases was 9.84, and among the vaccinated 5.09.

Figures I and II give the result of this work.

FIGURE I

TYPHOID PROPHYLAXIS

GERMAN AFRICAN EXPERIENCE 1904-1907

— KUHN —

Severity of Cases in Unvaccinated and Vaccinated

Type of Case	Unvaccinated		Vaccinated	
	No.	Per Cent	No.	Per Cent
Light	331	37	186	50
Moderately severe	225	25	96	26
Severe	234	25	65	18
Fatal	116	13	24	6

Early in the experimental work it was found that the age of the vaccine had considerable effect upon its immunizing properties. This no doubt accounted for some of the failures during the Boer War.

The strain of organism used by Leishman in his work was taken from a spleen at autopsy and was so old that it was thought at that time to have little virulence. Even in the early days there was some controversy as to whether or not a virulent or nonvirulent strain should be used. Wassermann and Strong both showed that virulence had little to do with producing antibodies in animals. Leishman confirmed this work and stated that vaccine made from virulent strains produced much greater constitutional reactions among those inoculated.

When vaccination was reintroduced into the British Army after 1904, Leishman reported the results in India among 19,000 troops, about half of whom were

vaccinated. The case incidence among the vaccinated was 5.39 per 1,000, while among the unvaccinated it was 30.4. The case fatality among the vaccinated was 8.9 per cent, among the unvaccinated 16.9 per cent.

In 1908, Captain F. F. Russell, Medical Corps, U. S. Army, was sent to Europe to make a study of the methods of inoculation for typhoid fever in use in England and Germany. Upon his return a board of officers was organized to investigate the advisability of immunizing our own Army. In addition to the Surgeon General and Russell, a number of prominent medical men, members of the Reserve Corps, were made members of the board. The board was actually composed of Surgeon General O'Reilly, as President, Captain F. F. Russell, Victor C. Vaughan, Simon Flexner, William C. Councilman, John H. Musser, Alexander Lambert, and William S. Thayer. Thus, with the exception of two members of the Regular

FIGURE IV

Army Medical Corps, the board was composed of leaders of the medical profession in civil life, who gave their valuable time to this work for more than a week, at very considerable financial loss to themselves, as a patriotic duty. Not only the Army but the whole country owes a great deal to these men.

The board was convinced that vaccination was both useful and harmless and recommended its introduction into the Army as a voluntary measure, especially among what was then called "the Hospital Corps" of the Army, the Nurse Corps, and troops taking the field.

On June 14, 1910, 92 men of Company A, First Battalion, Engineers, were vaccinated. On June 24, the company left Washington for Gettysburg, Pa., for maneuvers. The total strength of the company was 118 men. Ninety-two had received at least 1 dose of typhoid vaccine, 2 gave a history of typhoid, leaving 24 unprotected. On August 11, 5 days after returning home, 2 cases of typhoid appeared among the unvaccinated, and 4 others developed between the 20th and 23rd of that month, also among the unvaccinated. No cases developed among the vaccinated, while 25 per cent of the unprotected developed the disease.

FIGURE V—CAPTAIN F. F. RUSSELL

The first volunteers to take typhoid prophylaxis were medical officers stationed in and around Washington in the spring of 1909. Russell then desired to have it introduced among the troops. The first *organization* of the Army to submit to typhoid prophylaxis was Company C of the Hospital Corps, in the spring of 1909. At that time, as a Captain of the Medical Corps, I was in command of that company and Russell

FIGURE VI—Captain F. F. Russell giving the first typhoid vaccine at Army Medical School, 1911

asked me to try to get all the men to submit to the prophylaxis. The First Lieutenant of the organization was Mahlon Ashford (now Colonel, Medical Corps). There was no difficulty in persuading the men to take the complete series of injections, following a short address in which I explained to them the seriousness of typhoid fever, its mortality rate and some of the sequelae, and the expected beneficial results if the practice advocated by Russell were followed. Lieutenant Ashford gave me an injection and, in turn, I gave him one. Seeing the officers take it first no doubt was a factor in leading the men to submit themselves to the experiment. Ninety-five per cent of our company took the inoculation. They were promptly followed by Companies A and B of the Hospital Corps which, in turn, resulted in many officers and enlisted men of the line of the Army submitting to the inoculation.

In 1911, 2 brigade and 1 division maneuver camps were established in the southwest and vaccination was made compulsory among those troops. The results were excellent, and compulsory vaccination for the whole Army under 45 years of age was put into effect by General Order No. 134, War Department, September 30, 1911.

Figure XI presents graphically the number of cases and the deaths from typhoid fever beginning with the year 1897, through the years of the Spanish-American War, the World War and up to the present time. During the World War, in a mean annual strength of 4,128,479 men in the Army, there were only 1,529 cases of typhoid fever with 227 deaths. The distribution of these cases is shown in Figure X.

During the last 10 years we have had only 83 cases of typhoid fever in the Army. About a quarter of these occurred in 1931 among men of one battery of field artillery engaged in a practise march in the middle west, during which hygiene

was neglected. An analysis shows that in 14 there was no record of vaccination. Someone had "slipped up" when they were enlisted.

TYPHOID IN THE CIVILIAN CONSERVATION CORPS

The Civilian Conservation Corps came into being early in 1933. Men were examined at Army stations, vaccinated against smallpox and typhoid, and then sent to over 1,000 camps throughout the country, many of which were in endemic typhoid areas.

During the calendar year 1933, it is estimated that 450,000 men were in these camps at various times. The average strength for the 39 weeks was about 223,000, but many remained a short time or left at the end of their 6 months' service. Among this number there were 54 cases of typhoid fever with 4 deaths. Twenty-nine cases, with 1 death, occurred among men of one company in Texas, where working parties had used untreated water from shallow wells under very unsanitary conditions. An inspector stated:

Conditions in the environs of this house are indescribable and it is known that one case, at least, drank water in this house. It is also known that several of the men who are now infected and suspected, at least, drank from a spring from the northern slope, and that several others waded and even bathed in the stagnant puddles on the work site, although they admitted having been warned against the above.

While food and water were taken to these men by truck daily, in the ravine near their camp was a water course, to which the inspector refers, and which consisted mainly of stagnant pools. A few inhabitants lived along the ridges, poor people without any sanitary conveniences. In one wretched house lived a family of 7. All wastes of every description were freely thrown out or placed on the surrounding ground. In one house a year before there had been 2 cases of typhoid fever, with 1 death,

FIGURE VII

WHAT MIGHT HAVE HAPPENED FROM TYPHOID FEVERS DURING THE WORLD WAR HAD THE RATES BEEN THE SAME AS DURING PREVIOUS WARS

Number of Cases and Deaths

	<i>As Actually Happened During the World War</i>	<i>As Might Have Happened During the World War, Based on Annual Rates per 1,000 Strength During the</i>		
		<i>Civil War</i>	<i>Span. Am. War</i>	<i>Phil. Ins.</i>
Cases	1,529	143,052	623,607	47,849
Deaths	227	48,757	65,313	6,358

and laboratory tests showed that carriers were then living in this house.

When the Army began to make vaccine at the Army Medical School in 1909, a sub-strain of the Rawlins strain used by the British was obtained.

Much thought had been given to the selection of a proper strain by the British, particularly Leishman. The reasons for selecting this strain were

(1) low toxicity for guinea pigs and man, (2) satisfactory stimulation of certain antibodies, (3) produced uniform diffuse growth and was not agglutinated by normal salt solution.

Beginning in 1917, and from time to time since then, the efficacy of the Rawlins strain has been questioned. Weiss¹¹ challenged it on account of its inability to ferment xylose as a number

FIGURE VIII

of other strains did. This matter was cleared up later by showing that certain strains were slow fermenters and acted through the formation of "daughter colonies." Following this, objection was made because the so-called somatic or "O" type antigens were not produced in man in such concentrations as are observed after recovery from typhoid. That the titer of these "O" antibodies has a direct bearing on immunity is probably erroneous.

The latest objection to the vaccine grew out of a recent controversy as to the effectiveness of vaccine prepared from the so-called "rough" and "smooth" strains. Recently it has been shown that a strain of typhoid organisms may be made to produce either "rough" or "smooth" colonies under certain laboratory conditions. It may be interesting to cite a few cases where living typhoid bacilli were taken into the mouth in the laboratory:

In a case observed by Grant in 1921, an assistant working in the Eighth Corps Area Laboratory of the Army sucked into his mouth 0.5 c.c. of a heavy suspension of living typhoid culture strain K110. His mouth was washed out with 50 per cent alcohol and he was given 0.5 c.c. of Army vaccine. Four days later he developed headache and malaise, but there was no fever or other symptom except slight headache on the 8th day. Typhoid bacilli were isolated from the feces on the 12th day after the accident, and again on the 3 succeeding days, but none were found in the blood. This man had received the U. S. Army vaccine fourteen months previously.

In 1922, Sergeant George F. Luippold, Medical Department, while working in the Vaccine Department at the Army Medical School, swallowed approximately 25 c.c. of a saline suspension of the U. S. Army Rawlins culture containing about 3,000 million organisms per c.c. After rinsing his mouth with a cresol solution and with alcohol, he was given a subcutaneous injection of vaccine and kept in bed for one week. Cultures of stool, urine, and blood taken during this week were negative. On the 4th day he developed a temperature of 101, which disappeared after 2 days, and aside from a sore throat there were no other symptoms. Prior to this accident,

the Sergeant had received three complete courses of Rawlins vaccine, the last one 2 years previously, in 1920.

Major General Harry L. Gilchrist (retired), formerly Chief of the Chemical Warfare Service, and Colonel E. B. Vedder (retired), now Professor of Preventive Medicine at George Washington University, with 6 privates of the Medical Department, became ill with typhoid fever in August and September, 1904, during experiments with typhoid vaccine, being made to prove that killed broth cultures ingested were harmless. Unfortunately, they had not been heated at a high enough temperature to sterilize them, with the result that these 8 men contracted typhoid fever. Happily, there were no fatalities. General Gilchrist, at that time Captain in the Medical Corps, to encourage the men to take the dose with him, took twice the quantity taken by any of the others.

From the time of its introduction until July, 1917, the Army vaccine consisted of a saline suspension of the Rawlins strain grown on beef extract agar and killed by heating to between 53 and 54° C. for an hour. The vaccine was standardized at 1,000 million organisms per c.c. by the Harrison method, in which washed red blood cells were used for comparison. Later it was shown that by this method the actual bacterial count is only about one-half that of the count estimated by this method, so that during this period the vaccine consisted of approximately only 500 million organisms per c.c.

In July, 1917, 750 million paratyphoid "A" organisms and a like amount of paratyphoid "B" were added, Harrison's method of counting being used.

In July, 1919, the direct method of counting in a Helber chamber was adopted, which resulted in doubling the quantities of each component of the vaccine; and in April, 1920,

FIGURE IX

the nephelometer was introduced, using standards established by counts in a Helber chamber. The standards became more and more opaque with age, resulting in increasingly higher contents of the vaccine. This was not recognized until some time in 1923. Meanwhile the reactions had become so severe that in February, 1922, the paratyphoids were reduced to 500 million each, but as this was estimated by the nephelometer, there actually remained almost 1,500 million paratyphoid organisms. When the error in this method of counting was discovered in 1923, the actual count was approximately 1,750 million typhoid and a like number of paratyphoid organisms, a strength of 3,500 million as compared with the prescribed strength of 2,000 million. In March, 1924, vaccine was issued in which the direct count was 500 million typhoid and 250

million each of paratyphoid "A" and "B." At this time the Navy discontinued the paratyphoid fraction entirely and their vaccine was standardized at 1,000 million typhoid organisms and has been held at that since. The method of preparation of the vaccine at this time was also changed. Veal infusion agar was substituted for beef extract media and the killing point increased to 56° C. for 1 hour. In October, 1927, the paratyphoid "B" fraction for Army personnel was also discontinued and the typhoid fraction increased to 750 million per c.c. Beginning on April 1, 1934, the paratyphoid "A" fraction was discarded and the typhoid fraction increased to 2,000 million. This monovalent vaccine is the one now in use in the service. Recently, after an extensive investigation at the Army Medical School, Hawley and Simmons have come to the

FIGURE X

TYPHOID FEVER

DISTRIBUTION OF WORLD WAR CASES

There were no cases in Panama or Philippines among the white or colored troops.

conclusion that the Rawlins strain *may not be* the best typhoid vaccine strain, but it is their belief that the sub-strain used at the Army Medical School is no worse today than it ever was; nor has it been proved that the present state of this sub-strain is not the optimum for the prevention of typhoid fever in man, or that when the optimum dissociative state has been determined the Rawlins strain cannot be so maintained.

The new vaccine was issued so that it could be put into effect all over the country on April 1, 1934. Corps Area Surgeons were instructed to submit reports relative to the severity of reactions, etc., as compared with the old vaccine. As a result, a mass of material has been accumulated which is now being analyzed in my office.

Some reports state that it causes more reactions, and some less, while many note no difference. One of the most comprehensive reports (Fort Sheridan) shows a comparison between the old type of vaccine used at the second C.C.C. enrollment and the new which was used at the third. The figures are as follows:

	Number of Men Vaccinated	Number Admitted to Sick Report as Result of Reactions	Rate per 1,000
Second Enrollment	10,984	138	11.74
Third Enrollment	7,873	74	8.21

FIGURE XI

The Surgeon submitting this report states:

It is believed that the hospital admission rate does not reflect adequately the decreased toxicity of the new vaccine, as among men sent to hospitals the subjective symptoms were apparently much less disagreeable and the evidences of prostration were much milder than was formerly the case.

There seems to be considerable evidence that when reactions occur, they usually follow the second dose rather than either the first or third.

The result of typhoid prophylaxis in the United States Army is indicated most graphically in Figures VII, VIII, and IX.

During the World War more than 4,000,000 men were mobilized and among that great number there were but 1,529 admissions to sick report as the result of typhoid fever, or 1 admission for every 382 that occurred during the Spanish-American War in an Army averaging less than 207,000. Instead of our camps during the World War being hotbeds of infection, they were almost free from typhoid fever. In Manila, P. I., during the War Period (1917-1919 inclusive), there was but 1 case of typhoid fever among all the American and native troops, while among the civilian population there were 1.8 per 1,000 during each of these 3 years.

The man most responsible for this wonderful achievement, resulting in the saving of thousands of lives and the prevention of needless suffering to thousands of others, an accomplishment which was a real contribution in maintaining the man-power and the effectiveness of our Army during the World War, was Frederick F. Russell. He was the leader whose report of his observations and studies in Europe in 1908 convinced the board of distinguished scientists of the desirability and practicability of the introduction of killed cultures of typhoid bacilli as a means of producing protective immunizing bodies in man. The complete demonstration of the efficacy of this procedure in our Army on such a large scale served also to convince other armies of its value, and it was early introduced by the civil profession into their prac-

tice. In these days it is being carried out more and more as a routine public health measure.

While we are never justified in relaxing our general sanitary measures for the prevention of this disease, and it is known that at times typhoid prophylactic vaccination will not afford complete protection, particularly so against a gigantic or very virulent focus of infection, nevertheless when troops *do* contract typhoid fever in spite of prophylactic vaccination, the death rate is practically nil.

I have referred to the conclusions of Hawley and Simmons in "The Effectiveness of Vaccine Used in the Prevention of Typhoid Fever in the U. S. Army and Navy," in July, 1934, *American Journal of Public Health*. In view of their conclusions, it was the opinion of our immunologists that the Army vaccine could be improved by increasing its bacterial content, within the limits of safety. That is the reason we have reverted to a monovalent vaccine, as used between the years 1909 and 1917, though it is now more potent. To date the results have been excellent, as shown by its effectiveness among the large number of men who have been enlisted in the Army, and in other groups in this country.

The Director of Laboratories of the Army Medical School and his assistants are engaged in a series of careful investigations concerning the efficiency of the Rawlins strain now in use in our Army, with a view to ascertaining whether the same strain should be continued or a new one developed. This work will be carried on continuously over a long period. The present strain is working very satisfactorily wherever used in this country. However, there may be room for improvement, and the work indicated is going forward to reach a determination of this question.

Sickness Insurance of School Children in Switzerland

SICKNESS insurance of school children, as a supplement to insurance of adults, is required by law in 8 of the 25 cantons of Switzerland, among them Geneva and Saint Gallen; in 7 other cantons, including Bern and Zurich, such insurance is required only in some communes. In several cantons the insurance law applies only to children attending kindergarten or elementary public school; in others it applies to all children of certain ages, whether they attend school or not.

Each insured child pays into the insurance fund about 15 to 20 francs annually (\$2.80 to \$3.80); in case of poverty the payment is made by the commune; in addition the Federal Government and the cantons contribute together about half of this amount.

The purpose of the insurance is to provide medical attendance and medi-

cines in case of illness or accident; also when necessary special kinds of treatment, such as ultraviolet-ray, X-ray, or orthopedic. Undernourished children and those in need of recuperation or rest are sent to special resorts in the country or in the mountains. Parents or guardians failing to insure their children or wards are subject to penalties.

The number of insured children increased from 25,000 in 1914, when the social insurance law of 1911 went into effect, to 338,000 in 1932. According to recent reports from Switzerland, the system of children's insurance has been working well. The expected reserves have been accumulated; large numbers of children have been sent to rest homes; and the sick children have been supplied with all the necessary treatment.—*Le Assicurazioni Sociali*, Rome, vol. 10, No. 1, 1934.

Epidemiological Studies on Relapsing Fever in California*

HARLIN L. WYNNIS, M.D., AND M. DORTHY BECK

Chief, Bureau of Epidemiology, and Junior Epidemiologist, State Department of Public Health, San Francisco, Calif.

RELAPSING fever is an acute infectious disease characterized by attacks of fever followed by remissions during which the patient feels quite well, only to be seized again by relapses. The onset is generally acute, with chills, high fever, intense frontal headache, and excruciating pains in the back, limbs, and joints. Nausea and vomiting may occur and prostration is marked. The attack lasts from 2 to 4 days and is usually terminated by crisis, the temperature falling rapidly to normal with profuse sweating, and within a few hours there is an apparent restoration to health. The afebrile periods last from 3 to 12 days. Without specific treatment there are generally 2 to 4 attacks, occasionally as many as 8, each of decreasing severity. One injection of neoarsphenamine is considered sufficient to effect a complete cure. In California the disease may be confused with influenza and malaria. However, there is a leucocytosis in relapsing fever and quinine has no effect on the course of the disease.

Relapsing fever is caused by *Treponema recurrentis*. This organism is a long slender flexible spiral filament, tapering at both ends. It is 10-20 microns long and usually has about 8

undulations, occasionally as many as 10 or 12. Long chains are sometimes observed, being arranged end to end. It is actively motile. The laboratory diagnosis of relapsing fever is either by blood smears or animal inoculation. The blood smears may be stained by the methods of Wright, Giemsa, or gentian violet. These methods are satisfactory during the febrile period when the organisms are usually found in abundance, but during remissions or at other times when they cannot be demonstrated by stains it is necessary to resort to animal inoculation. The patient's blood may be immediately inoculated into white mice or may be shipped as clotted blood to the laboratory. Our observations show that the spirochetes remain viable un-iced for as long as 6 days.

In the California group of cases there have been no serious complications or sequelae and no deaths. This is in contrast to the epidemic louse-borne type seen in the Old World where the mortality may be as high as 50 per cent or more.

While the disease is very common in various parts of the world and often reaches epidemic proportions, there have been relatively few cases in the United States. In 1844¹ the first cases were reported in Philadelphia, and for a number of years the disease appeared in Eastern United States, where the last epidemic was reported in 1869.

* Read before the Epidemiology Section of the American Public Health Association at the Sixty-third Annual Meeting in Pasadena, Calif., September 3, 1934.

In 1875, Dr. P. B. M. Miller gave an account in the *Pacific Medical and Surgical Journal*² of an epidemic of relapsing fever among Chinese laborers at Oroville, Calif. This prevailed during the months of August, September, and October, 1874, and it was estimated that there were several hundred cases. No further mention is made in the literature of this disease in California until 1906, when 2 deaths were recorded

in the *19th Biennial Report* of the State Board of Health³ and in 1907, 1 death was reported in the *20th Biennial Report*.⁴ There is no comment on these deaths as to the geographic distribution or laboratory diagnosis.

The first proved cases were described by Dr. LeRoy Briggs⁵ of San Francisco, in 1921. These patients were infected at Polaris, near Lake Tahoe. They were proved positive by blood smear examination. Reports of one or two cases yearly are on record in the files up to 1930, when 4 were brought to the notice of the California State Department of Public Health. In July, 1931, the State Board of Health, recognizing the public health importance of the disease, passed a resolution making it reportable and to date (August 18, 1934), 69 cases have been recorded.

In Table I the group of cases shows twice as many males as females, which is comparable to the incidence in the Old World. There, the variation is attributed to differences in chances of ex-

* Owner of fox farm. Pelting done in February

† No laboratory confirmation

‡ Laboratory infection

posure but in our series of cases no such explanation is plausible. All ages from 4 years to above 55 are represented.

According to dates of onset the majority of cases occur in June, July, and August. This is also true in Texas, as contrasted with the epidemic louse-borne form which is more prevalent in the winter months. The occurrence of cases runs practically parallel with the appearance and disappearance of rodents. Table II shows the cases by years and months of onset. Two cases

are recorded in February. One of these patients owned a fox farm. The animals are pelted in February and during the process the operator receives many scratches and cuts. It is possible the infection was passed by direct transmission from these foxes. This was not proved, as blood was not obtained from these animals at the time of pelting. The second case reported in February was not confirmed by laboratory methods and is open to question. The April case was contracted through a

laboratory accident. One case had its onset in May, 1934, but this year the season was far more advanced than normal which may account for this.

The geographical distribution of human cases is of decided epidemiological interest (see Map A). Sixty-six of the cases recorded have occurred in 4 foci of the state: Lake Tahoe, Packer Lake, Strawberry Lake, and Big Bear Lake. These districts, as may be noted on the map, are in widely separated mountainous sections at elevations of 5,000 feet and over. The topography in all is similar. The mountains are heavily wooded and abound in animal life. The winters are rather severe with heavy snowfall usually lasting until late May or early June, while the summers are warm and pleasant, which makes these districts popular as resorts. Many wealthy people have summer homes around the lakes. The dates of onset of recorded cases correspond roughly to this seasonal change, to the return of animal and insect life, and to the sudden increase in population due to the influx of those on vacation. There is considerable evidence that the disease has long been established and is prevalent in these areas, as the natives speak of "squirrel fever" which is undoubtedly relapsing fever.

The possibility of an animal reservoir of *Treponema recurrentis* presented it-

self. Surveys were made in 3 of the foci: Big Bear Lake, Lake Tahoe, and Packer Lake in an attempt to determine the animal reservoir and the agent that may transmit the disease (Map B). The field work was started in the spring as soon as weather conditions permitted and the rodents were present in sufficient numbers. A mobile laboratory unit was used. Table III gives a summary of the rodents examined. Included under "other animals" were tree squirrels, Oregon fuzz-tail squirrels, rabbits, rats, mice, fitch, fox, woodchuck, weazels, bats, and birds. A total of 905 animals were examined for the presence of *Treponema recurrentis* in the two surveys 1931 and 1932. In the 1932 survey, 13 strains of spirochetes were isolated from these rodents⁷; 2 strains from tamarack squirrels; and 11 from chipmunks. The same species of rodents were found to harbor spirochetes in the 3 foci investigated.

A comparative study was made of the rodent and human strains to determine if they were identical. Morphologically the organisms from both sources appear to be the same. The field incident in which there appeared to be direct transmission of spirochetes from a tamarack squirrel to a member of the survey crew offers further proof that the two strains, animal and human, are identical.^{6, 7} Mr. X accidentally contaminated an open

wound on his hand with blood from a squirrel recently shot, which later was proved positive for spirochetes. Seven days later he developed a clinical case of relapsing fever and similar spirochetes were demonstrated in his blood. Experimental work now in progress in this department, which will be reported later, seems to support the evidence that the spirochetes found in tamarack squirrels and chipmunks are identical with those found in patients associated with them, and that these rodents act

as a reservoir of infection for relapsing fever in California.

Nicolle and Anderson⁸ as a result of their extensive observations on relapsing fever in Tunis have developed the interesting hypothesis that blood spirochetes were originally parasites of small burrowing mammals and that rodents commonly serve as animal reservoirs of the disease. This is comparable to our observations, *i.e.*, positive findings in chipmunks and tamarack squirrels.⁷ The disease is transmitted

through the agency of ectoparasites such as various species of *Ornithodoros* according to the above authors. Clark, Dunn, and Benavides⁹ also suggest that relapsing fever is primarily a disease of animals and that man is only an accidental host—probably attacked by ticks as a matter of necessity.

In Texas, relapsing fever is transmitted by *Ornithodoros turicata*¹⁰ and in Panama by *O. talaje* and *O. venezuelensis*.¹¹ This means of transmission seems to be the most likely in California because of the following facts: (1) the endemicity of the disease, (2) seasonal distribution (3) class of people affected and their living conditions, (4) geographic distribution. The case histories were studied for reports of insect bites. Of the 69 patients 24 reported bites of some description caused by ticks, mosquitoes, fleas, and possibly bed bugs and other insects. In only a few instances could ticks be definitely incriminated. This may be because: (1) the larval and nymphal stages of these ticks are responsible for the transmission; (2) these forms are small in size, having been compared with the seeds of a strawberry; (3) ticks of species *Ornithodoros* do not remain attached after completing a blood meal; (4) after feeding, these ticks conceal themselves and hibernate, perhaps for months, therefore would be most difficult to find. A series of 5 cases reported in British Columbia¹² gave no history of insect bites, which might indicate that the problem there is similar to ours. As part of the epidemiological study in this state all the animals surveyed were examined for ectoparasites, with negative results except for fleas and lice. The burrows and nests of rodents were searched for ticks as were also the homes of patients. At Lake Tahoe nymphal forms of *O. turicata* were discovered in a cabin where a case had developed, and, associated with a number of cases, nymphal

forms of *Ornithodoros* (identification not completed) were found at Big Bear Lake. *O. coriaceus* was also found at Lake Tahoe. These specimens, however, were so limited in number that very little experimental work could be accomplished, and definite proof that these ticks are infected in nature is lacking in this state.

The California situation seems to be directly opposed to the epidemiological findings in Texas and Tropical America, in both of which places ticks of the species *Ornithodoros* are very prevalent; the native huts in Panama often yielding large numbers (4,880 specimens from 68 huts)^{11, 13} and certain caves in Denton County, Tex.,¹⁰ have supplied ticks in abundance. In California, the ticks are found with great difficulty and never in large numbers. If ticks were as numerous in California as in Panama and Texas, more cases would undoubtedly be reported because of the high incidence of infection found among wild rodents (chipmunks and tamarack squirrels). All indications in California are that the ticks hibernate during the winter with these rodents and become infected from feeding on their hosts, and are disseminated in the spring at the time the rodents become active and leave their nests.

Altitude seems to play a very important part in California, as the cases have been confined to mountainous districts over 5,000 feet in elevation. There is apparently no such limitation to the incidence of the disease in Panama and Texas. The actual elevation, however, is of less significance than the climatic factors present in these particular locations. The wild rodents, chipmunks and tamarack squirrels, in which spirochetes resembling *Treponema recurrentis* have been found are limited to these higher altitudes also, which is strong evidence that they act as the animal reservoir of relapsing fever in this state. On the other hand, the

species of ticks incriminated is probably not limited to the high altitudes. So, in explanation of the peculiar distribution of endemic foci in our state the suggestion is offered that it is determined by the animal reservoir rather than by the transmitting agent.

SUMMARY

1. Relapsing fever has been reported in California since 1874.

2. It is endemic in this state, 69 definite cases having been reported from 1921 to August 18, 1934.

3. Seasonal distribution is marked—the majority of cases occurring in June, July, and August.

4. Sixty-six of the 69 cases have been reported from 4 foci; 2 of the remaining 3 were of unknown source and the third was a laboratory infection.

5. The 4 foci are all mountainous districts over 5,000 feet in elevation and popular as summer resorts.

6. The same wild rodents (chipmunks and tamarack squirrels) have been found to harbor spirochetes resembling *Treponema recurrentis* in 3 of these foci. They probably act as the reservoirs of infection.

7. No definite vector has been determined. Ticks of the species *Ornithodoros* have been obtained at Big Bear Lake and at Lake Tahoe associated with proved cases of relapsing fever.

Test for Protective Power Against Yellow Fever

A METHOD of testing sera for protective power against yellow fever is described and designated as the intraperitoneal protection test in mice. The test consists essentially of the inoculation of mice intraperitoneally with yellow fever virus, fixed for mice, together with the serum to be tested, and the simultaneous injection of starch solution into the brain to localize the virus. If the serum lacks protective power the mice die of yellow fever encephalitis.

The test is highly sensitive. Consequently it is useful in epidemiological studies to determine whether individuals have ever had yellow fever and in tests to find whether vaccinated persons or

animals have in reality been immunized. When mice were given large intraperitoneal injections of yellow fever virus fixed for mice, the virus could be recovered from the blood for 4 days although encephalitis did not occur. If the brain was mildly injured at the time of the intraperitoneal injection, the symptoms of yellow fever encephalitis appeared 6 days later, but the virus was then absent from the blood. Strains of white mice vary greatly in their susceptibility to yellow fever. W. A. Sawyer and Wray Lloyd. *The Use of Mice in Tests of Immunity Against Yellow Fever. J. Exper. Hydrocyanic Acid Gas and Other Toxic Gases in Commercial Fumigation*

AIMÉ COUSINEAU, F.A.P.H.A., AND F. G. LEGG, F.A.P.H.A.

Sanitary Engineer, Department of Health, Montreal, Canada; and Sanitary Engineer, Department of Health, Detroit, Mich.

THIS joint paper summarizes the study made by officials of Detroit and Montreal, working independently, on behalf of their respective health departments, to draw up safe and practical fumigation regulations for the effective destruction or control of vermin.

Fumigation is a process of sanitary significance, in which a lethal gas is confined in an enclosed space, to destroy insect life in all stages and rodents.

GENERAL CONSIDERATIONS

Theoretical considerations related to the subject of fumigation, such as the laws of gaseous diffusion, the penetrating power, and the stratification of gases, etc., will be referred to but will not be discussed. In this respect, sanitarians must depend upon the available scientific data, although heterogeneous in nature, based on fundamental principles, but which must be interpreted and applied, to the view of safeguarding human lives.

The conditions of fumigation, save for climatic differences or variations, are relatively the same in all cities; but no standardized regulations are yet existent in the United States and Canada.

Because this material is not available, much study is required to correlate the useful information on the subject, especially that on warning gases, which has been the subject of considerable controversy in the past few years. In a study of this nature, it is logical to include the fumigants under consideration among the known noxious gases, and, to this end, no better classification is available than that given by Henderson and Haggard¹ who have placed cyanide gases used in commercial fumigation among the group of asphyxiants, the latter group being subdivided into "simple asphyxiants," or physiologically inert gases, like nitrogen and hydrogen; and "chemical asphyxiants," or substances which, by combining with the hemoglobin of the blood, stop oxidation in the living tissues, so that the oxygen cannot be utilized and death from asphyxia soon occurs.

Hydrocyanic acid gas (HCN), and cyanogen gas (C₂N₂), being in the class of "chemical asphyxiants," must be handled with great care by competent operators, and according to well established procedure.

Every city of any importance must, sooner or later, in the interest of safety, enact ordinances or regulations to prevent unnecessary fatalities which are due mainly to ignorance or negligence in conducting fumigation operations.

Experience of the past 25 years has

* Read before the Public Health Engineering Section of the American Public Health Association, at its Sixty-third Annual Meeting in Pasadena, Calif., September 3, 1934.

demonstrated the effectiveness of various toxic gases, when employed as fumigants for the extermination or control of pests common to certain classes of industry, and those classed as "household pests," the presence of which is extremely annoying to human beings. Governmental agencies have, from time to time, published bulletins for general distribution in which the recommended methods for the control of various insects, rodents, and pests have been explained in great detail. Poisons, spray compounds, gases of varying toxicities, powders (poisonous and non-poisonous) are the recommended vehicles by which the vermin are eliminated. The information contained in these bulletins has been a great boon to mankind in that it has supplied individuals with the knowledge necessary for the solution of their particular problems. On the other hand, it has stimulated the use of toxic gases, the employment of which is accompanied by greater hazards than the layman understands. Experience has indicated that the promiscuous use of this knowledge has resulted in a loss of life sufficient to prompt official cognizance of fumigation hazards with the enactment of legislation designed to insure greater safety to the public.

We believe that of all the toxic gases employed for exterminating purposes, hydrocyanic acid gas (HCN) is conceded to be the most dangerous. Its deadly character, coupled with the fact that its slight characteristic odor is not detected by the average person, renders any error in the technic of its use extremely hazardous.

Any attempt to discourage the use of a gas that has become more or less the standard for exterminating purposes, on the grounds that there are less hazardous methods of accomplishing results, has met with a great deal of opposition. In the first place, there appears to be a difference of opinion among the better

informed as to the necessity for restricting the use of straight HCN, other than to require that its use be subjected to control by licensing operators and its application subjected to strict regulations governing technic.

Detroit was one of the first cities which attempted to control the use of toxic gases in exterminating practices. The first ordinance was enacted in July, 1921. This legislation has been amended several times in an effort to decrease the deaths and accidents attributed to the use of HCN. The regulations in effect for a number of years have embodied the standard requirements, such as: the examination of all persons as to their qualifications before licensing them to employ the gas; the filing of an approved \$1,000 indemnity bond; the reporting of every operation to the Department of Health; the complete vacating of the entire independent structure, any portion of which is subjected to the gas; the placarding and guarding of the structure during the period of gasing and ventilation; prohibiting children to reënter until the following morning; a minimum airing period of 2 hours or until all traces of the gas have disappeared and the structure is pronounced safe by the licensed fumigator.

In spite of these regulations, guards are unreliable and inefficient, and unsuspecting persons enter to their death. Persons disregard the caution to keep windows open and in closing them create potential death chambers.

Fifteen deaths have occurred in Detroit since 1921, and in Montreal 8 recorded deaths since 1928, all of which have been positively attributed to HCN in fumigations. During this period it is estimated from available records that no less than 30,000 separate jobs were undertaken in Detroit in which this gas was employed. One death per 2,000 fumigations performed, the approximate average for Detroit, would probably

represent the normal accident expectancy in any community.

The circumstances under which the deaths occurred indicate that negligence of some degree was a contributing factor in every case. There are so many things that may happen on a given fumigating job to create a potential hazard that it is not possible to predict the ones most likely to occur.

If regulations and rules of conduct are made too rigid, there will be no fumigations performed with HCN except those undertaken surreptitiously. This statement is based upon the fact that in the last analysis the cost of exterminating in a given case will determine the method to be employed, provided, the property owner or manager is convinced that the particular method used is to be effective.

Under similar rules of procedure an operator employing cyanogen chloride (CNCI) in fumigation cannot compete with one employing straight HCN on account of the difference in cost of the ingredients, inconvenience in handling, and greater care necessary in sealing the spaces to be fumigated. Straight HCN released by the pot method is without doubt the cheapest, most effective method of exterminating certain household pests.

To contend, as do some exterminators, that there are no other reliable methods available to accomplish comparable results is unwarranted; yet, such assertions have been made before legislative bodies by interests opposed to any interference with the practice of releasing straight HCN for exterminating purposes.

It may be a fact that there are no other methods as effective at the same unit of cost, but, on the other hand, there are no other methods that constitute an equal hazard to human life. The question which is to be settled is, therefore, one of cost as balanced against safety.

Those engaged in the business of exterminating and who employ HCN as the principal fumigant, placing very little reliance on sprays and powders for the effectiveness of their operations, are very anxious to have all persons engaged in exterminating licensed for the purpose of control. It is alleged that the method which they employ are sufficiently hazardous to warrant supervision.

Granted that there is the possibility that roach powders may be so carelessly spread as to poison food or be eaten by infants or small children and that various sprays may create a fire hazard, the Detroit experiences over a period of 13 years have not been such as to place the spreading of insecticides, the use of pyrethrum sprays, or the burning of sulphur in the same category *with the use of HCN*.

The U. S. Public Health Service, under whose jurisdiction ship fumigation is conducted, has experimented with various gases, and from information obtained from the Bureau it is apparent that the authorities are of the opinion that the so-called warning gases are desirable. However, the greatest degree of protection to the public as regards the use of lethal gases for domestic fumigation is, they believe, afforded through the adequate control of the concerns and employees engaged in the business, the products to be used, and the premises in which they are used.

From an analysis of the accidents in Detroit and Montreal over a period of several years, from close observation of the actual effectiveness of CNCI combination with HCN as a practical warning in fumigation, the Detroit and Montreal health authorities have concluded, and are on records, that the use of straight HCN in the fumigation of dwellings for exterminating purposes, should be prohibited, and that lethal gases employed in fumigation be mixed with an approved warning expulsive gas,

or be of themselves warning expulsive gases.

An ordinance in line with this policy was recommended to the Detroit Common Council in July, 1933. To date, objections on the part of commercial fumigators and chemical manufacturers, together with the conflicting opinions of authorities as to the value of warning agents in fumigation, have succeeded in delaying legislative action recommended as a safety measure by the Detroit Board of Health.

Public opinion showed alarm in Montreal over this same matter, during the past few years, and proper legislation was sought. To the Health Department of this city was entrusted the task of preparing and enforcing ordinances, based on the best available scientific information and on the existing legislation.² This has brought up important considerations regarding the basic principles of the subject of fumigation, especially of warning gases. It is now hoped that a consensus of opinion on the latter will soon be reached—first, as regards their necessity; second, as regards the relative value of those gases which are in most common use; third, as regards the results obtained in safeguarding human life, with or without the use of warning gases.

STANDARDIZATION

Along the line of standardization of fumigation ordinances, good work has been accomplished by the National Fire Protection Association,³ and reports have been made at their 1933 and 1934 meetings, held in Milwaukee and Atlantic City respectively. The above regulations which pertain mainly to fumigation hazards, do not contain any reference in regard to the use of warning gases.

This omission may be attributed to the fact that these regulations were drafted with the main view, that fumigation processes introduce fire hazards, as

illustrated in Factory Mutual Data sheet 11-91-31:

Nearly every fumigation process introduces a serious fire hazard, either because the fumigant is flammable and creates an explosive atmosphere or because it is extremely toxic and curtails or prevents effective fire fighting.

The same divergence of opinion exists in regard to the subject of cross-connections in water supplies. Sanitarians require their complete severance, while, for safety purposes, fire protection associations are inclined to permit their use under certain conditions.

The Bureau of the U. S. Public Health Service may take a stand in the near future in reference to the use of warning gases in the fumigation of inhabited buildings, which stand would lead, no doubt, to the standardization of fumigation ordinances.

Provisions have been made in the Montreal fumigation by-law,⁴ to meet such eventual developments; the proposed Detroit new regulations have also included these necessary provisions.

MONTREAL FUMIGATION ORDINANCE

In the Montreal enacted ordinance, "fumigant" is construed to mean, not only "hydrocyanic acid in any form whatsoever," but as well, "any other substance as may be specified by the Director of the Health Department."

Moreover, the use of "fumigants" derived from hydrocyanic acid or its compounds is prohibited in inhabited buildings, unless they are associated with a warning gas, such as cyanogen chloride in the proportion of at least 30 per cent. Warning gases other than cyanogen chloride with their relative proportions to the fumigant used, may, however, be approved by the same authority, provided they give, in "non-dangerous concentrations, a sufficient and non-equivocal warning and render the stay unbearable in the dangerous zone, etc."

DETROIT FUMIGATION ORDINANCE

The Detroit proposed new fumigation ordinance which is being considered by the authorities of the city, contains the following provision in regard to warning gases which has been proposed, after the U. S. Public Health Service has given the assurance that it will co-operate with health departments in the approval of such gases:

The use of poisonous gases, fumes or vapors in fumigation is hereby prohibited, unless the same are mixed with a warning expulsive gas, or are in themselves warning expulsive gases. Such gas, gases, fumes or vapors or combination thereof, shall be such that the Department of Health of the City of Detroit and the United States Public Health Service approve them as giving sufficient warning to human beings in less than dangerous concentrations, as to create sufficient discomfort to have a definite expulsive effect, etc.

According to H. J. Langhorst, fumigation expert, ideal warning gases are those which have relatively the same specific gravity, vapor density, and penetrating power as HCN. Mr. Langhorst admits at the same time, that such gases are not to be found, but much to be desired.⁵

Warning gases are much heavier than air while HCN is slightly lighter than air; HCN diffuses 1.5 times as rapidly as CNCl, and twice as rapidly as chloropicrin. Warning gases have lower penetrating power and may be aired out before HCN has been completely liberated, and hence it is thought that the post-warning effect is not reliable. It would appear, however, according to Williams⁶ that such gases may be of value in preventing accidents in those cases where the fumigant gas has passed through unsuspected openings, from one building to another, and, without doubt, where unwarned persons are entering into premises under fumigation.

We fully realize that the warning gases now being used are not entirely reliable, but we are inclined to believe that the objections to their use are not

serious enough to outweigh the advantage of such a practice provided, however, that all the known precautions are taken as well.

As to the relative value of warning gases in commercial fumigation, it is only necessary to consider the case of CNCl and of chloropicrin, as all the other warning gases have not proved so reliable, because of their too great difference in molecular weights as compared with HCN.

The molecular weight of chloropicrin compared to HCN is so different that it cannot constitute a satisfactory warning gas; its characteristics are such that complete separation of the gases may follow as soon as liberated. Moreover, the tear effect remains after the room or compartment has been cleared of HCN and prolongs the clearing out of fumigated rooms when mixtures of above 5 per cent chloropicrin are being used. Nevertheless, the above disadvantage may not outweigh in industrial or ship fumigation the practical advantage gained with the use of simple means or improved methods.

CHLOROPICRIN

Due to their commercial availability other forms of HCN, Zyklon B, HCN Discoids, Cyanogas (calcium cyanide), and liquid HCN, with 5 per cent chloropicrin, have replaced to a certain extent cumbersome generative methods in ship fumigation.

It is to be noted that the problem of house fumigation differs widely as to hazards involved, compared with ship fumigation performed under the supervision of medical officers and a specially trained personnel which has undergone a course of instruction, followed by practical and theoretical tests on the use of lethal gases. Moreover, the danger zone in ship fumigation, is limited to its enclosed space, and the strict ship discipline contributes largely also to the elimination of fumigation hazards.

HCN-CNCL MIXTURE

Although the above methods and fumigants may also be convenient in household fumigation, they do not offer sufficient guarantee for safety and health, as the tear or lachrimating elements contained in these products do not give positive warning.

The cyanogen-chloride mixture, on the other hand, has been found to give positive warning, even in sub-lethal concentrations, and possesses in addition nearly all the characteristics of HCN as a fumigant. The above mixture is not only an insecticide but a germicide as well.

As far back as 1923, an amendment (No. 6) to the U. S. Quarantine Regulations, Public Health Service, was authorized, and since then the cyanogen chloride mixture was added to the list of permitted gaseous agents.

Suffice to cite here part of paragraph 179A, contained in the amendment:

Cyanogen chloride mixture when used in concentrations, for the length of exposure recommended in these regulations, and by experienced fumigators who avail themselves of the safeguards furnished, is not believed to be attended with any greater hazard than the use of sulphur dioxide.

As to the separation of the constituents of the HCN-CNCL mixture, under ordinary conditions of use, we may quote the following authorities:

Pease: The gas generated at any one time is a mixture of the two gases in the same sense that air is a mixture of (essentially) two gases, oxygen and nitrogen, and that there would be no possibility of any separation taking place under ordinary conditions of use.⁷

Stead: HCN and CNCL may be generated on the premises by adding sodium cyanide and sodium chlorate to HCL in the proper proportion.—The final product is $\frac{1}{3}$ HCN and $\frac{2}{3}$ CNCL by weight, presumably tied together with a chemical bond.⁸

Frazer: If HCN and CNCL are left for a sufficiently long time to reach equilibrium by diffusion, it will be impossible for them to separate or change concentrations, except as they may diffuse from the hold and escape, and here again the same factors will govern,

the lighter gas diffuses more rapidly than the heavier.⁹

Finally as to the relative value of the two warning gases in most common use, CNCL and chloropicrin, it may be of interest to quote here the following extract from a report, prepared by Williams, Hosendorf, and Redlon of the U. S. Public Health Service, on the Fumigation of Vessels:

Both of the warning gases which have been used with liquid cyanide produce a tear effect. The effect of the 20 per cent cyanogen-chloride gas is greater than that of 5 per cent chloropicrin, *i.e.*, lachrimation is much more marked; and it is believed that, on account of the tear effect, a person unfamiliar with fumigation could escape from a small room containing hydrocyanic-acid gas with 20 per cent cyanogen chloride before inhaling a dangerous amount of cyanide.

The lachrimation which is produced by 5 per cent chloropicrin is much less, and even when used by experienced fumigators it would seem desirable to have a more pronounced warning effect, etc.¹⁰

In an endeavor to complete our information with the aid of the available data on the subject of fumigation, and on warning gases, in particular, we have obtained various other personal opinions from officers and former officers of the U. S. Public Health Service of which we will take the liberty of summarizing a few:

1. *Cumming:* It is the consensus of opinion of the officials of the United States Public Health Service who have given consideration to this matter, that a warning property in a fumigant is of distinct advantage in the prevention of accidents. It is realized that the gas added to hydrocyanic acid at the present time to give the resulting fumigant a warning property, does not have all the characteristics needed; however, until a satisfactory agent is developed it should be used.¹¹

2. *Cumming:* It is the consensus of opinion of officers of the Public Health Service that the use of straight hydrocyanic acid gas for fumigation of buildings or other enclosures should be prohibited. . . . In answer to your question as to the warning agent referred to in my previous letter, this gas was chloropicrin: however, this will apply similarly to cyanogen chloride. Patents on

the use of this latter have been assigned to the Treasury Department and held by the Public Health Service.¹²

3. *Cumming*: It is to be observed that all of the warning gases at present in common use (cyanogen chloride, chloropicrin) are approximately twice as heavy as hydrocyanic acid and under some conditions separate from a mixture of the two gases. Usually this occurs where the gas mixture penetrates further and more rapidly than the warning component. . . . The question of requiring the mandatory use of a warning gas in connection with the application for fumigation purposes of a lethal gas is quite involved and cannot be met simply.¹³

4. *Creel*: Judging from my experience of the last 20 years, I should say by all means, that any laws or regulations governing commercial fumigation of buildings in any city, should provide for automatic safeguards, such as a lachrimating element in all fumigating gas.

HCN-CNCl mixture was first used at San Francisco Quarantine the fall of 1922, and for the 4 years I was at the station fumigating an average of 600 vessels a year, there were no accidents whatsoever, nor so far as I know have accidents ever occurred aboard ships where CNCl was employed.¹⁴

5. *White*: Regarding my personal opinion as to the fumigants, I may state that I consider cyanogen chloride mixture, containing at least 35 per cent warning gas, as the only safe and fool-proof gas in use today. I have never learned of any accident from the use of it on ships.¹⁵

6. *Houghton*: Judging from our experience of the past 5 years, we have retailed 50,000 units of our Safri-Fume (HCl-CNCl mixture), without one case of an accident being recorded.¹⁶

In accordance with the carefully considered policy of the Health Department of the City of Boston where the above fumigants have been mainly used, no attempt to regulate fumigating has ever been made.

STUDY OF AVAILABLE DATA PREVIOUS TO THE PREPARATION OF FUMIGATING ORDINANCES

Following a careful study of all available data, the Montreal fumigation regulations have been drafted, above all, in the interest of safety and public health, regardless of the commercial

availability or serviceability of marketed products.

In a general way, the regulations are written in the by-law, but discretionary power is given, in certain cases, to the Director of the Health Department.

The Montreal ordinance dealing with the question of lethal gases, being the most recent piece of legislation on this subject, covers every possible contingency. It includes 41 articles, grouped in 5 chapters, referring to definitions or interpretation of the terms used, certificate of competency, permits and licenses, materials and mode of proceeding; enforcement, and finally, to penalties for contravening any of its provisions.

Among the interpretative clauses which are of interest to cite here are those relating to "fumigant," "nuisance," "danger zone," and "vermin."

"*Fumigant*" is construed to mean hydrocyanic acid in any form whatsoever, or any other substance as may be specified by the Director of the Health Department generated in a building or supplied ready prepared as a liquid, or in a solid form, and which, by itself or in combination with other substances, emits or liberates a gas or gases, fumes, or vapors liable to cause a nuisance.

"*Nuisance*" means any act or omission which may endanger the life, safety, health, property, or comfort of the public of an individual or individuals, or by which the public or any individuals are obstructed in the exercise or enjoyment of any right common to all His Majesty's subjects.

The meaning of the word "fumigant" being well established and its use permitted only on the explicit condition that it will not cause a nuisance as defined above, the boundaries of the "danger zone" had to be extended not only to the rooms within the walls of building, from cellar or basement to the roof level, but in addition, the adjoining ground and any contiguous room in adjoining building, or to any building, the occupants of which are so exposed as to be subjected to a nuisance from fumigation.

Fumigation having for its object the destruction or control of "vermin," this term has been defined as "any insect and other animal pest found in or about a building, which attacks human beings, or domestic animals, or foodstuffs, or organic refuse, or clothing, or bedding, or furniture, etc., namely: flies, bed-bugs, fleas, lice, rats, mice, cock-roaches, ants, moths, worms, mosquitoes, spiders, crickets, bats, wasps, ticks, etc."

One of the most important phases of any fumigation ordinance, is that which refers to effective provisions for the qualification and responsibility of persons carrying on fumigation operations.

An examination is required to obtain a certificate of competency from a Board of Examiners, specially named to that effect, which consists of the necessary tests to ascertain the training, experience, and fitness of applicants for licenses, as well as their acquaintance with the provisions of the regulations in force, their knowledge of the methods of resuscitation, the toxic action of fumigants, etc., and finally, a medical certificate from every operator, showing that he is in good health.

Three types of licenses have been provided in the Montreal by-law which entitle the respective holders thereof to perform certain operations:

1. *Master-fumigator*: If duly qualified as fumigator, or having in his employ at least one operator qualified as such, to keep or operate a bona fide fumigation business.

2. *Fumigator*: To conduct fumigation operations for a master-fumigator.

3. *Journeyman-fumigator*: To work under the immediate supervision of a licensed fumigator.

The above licenses are granted by the Director of Finance only when a permit or a written authorization is obtained from the Health Department. A certificate of competency, as referred to above, is required to obtain a license. If issued to a master-fumigator, a real estate bond, or indemnity bond, or public liability insurance policy, in the sum

of not less than \$10,000, must be furnished to the city by the applicant for the benefit of any one who may suffer injury, etc.

Licenses may be refused or revoked. In case the licensee be convicted for a third time before the Recorder's Court, of any infraction of any provisions of the fumigation ordinance or, for the first time before a higher Court of criminal neglect, his license is *ipso facto* revoked and cannot be renewed.

It is explicitly stated in the by-law and fumigators are required to take notice, that licenses issued, etc., do not bind the city; or place upon it any liability in regard to the processes used or their application, and that the licensees alone must assume the entire liability, criminal or civil, to which they may be subject by reason of general laws, in case of death, personal injury, illness, or property damage by fire or otherwise.

The owners or occupants of commercial or industrial establishments, using fumigants on their own premises, or in connection with the material contained therein, are exempted from obtaining a license, but are required to obtain a certificate of competency; the employees of the Federal and Provincial Governments and of the city, in the performance of their regular duties, do not fall under the jurisdiction of the present regulations. Ship fumigation is controlled by the Quarantine Service of the Department of Pensions and National Health, and are, hence, outside the jurisdiction of the present regulations.

MATERIALS AND MODE OR PROCEEDING

Before fumigating any building in Montreal, the master-fumigator is required to give notice to the Health, Police, and Fire Departments, in the form of a written statement to the effect that he has obtained the authorization in writing of the proprietor and

of all responsible occupants of the buildings to be fumigated, and that he has warned all other responsible occupants of the premises situated within the dangerous zone, of the nature of the operations to be performed on the day and at the time designated.

No provisions have been made for the delivery of a permit to a master-fumigator, to perform fumigation in a specified building, and at a specified time, as no such permission can be given, unless the premises concerned are previously thoroughly inspected by city inspectors—this is left entirely to the licensees. Otherwise, a share of the responsibility in case of accidents or fatalities could be attributed to the enforcing authorities.

As stated above, the fumigators must assume the entire liability in regard to the processes used and the operations carried on, the notification procedure being required only to enable the city to ascertain whether the operators are offending against any of the enacted provisions.

The conditions under which the fumigation operations should be carried on need not be stressed, as they are similar in all ordinances and conform to established practice—sealing of rooms to confine the gas to the fumigated premises; warning signs; guards stationed around the building; removal of food; extinguishing of fires; opening of rooms after fumigation; beating or shaking of articles of bedding, ventilation before re-occupancy, and other operations usual in the practice of fumigation.

The operator should allow a sufficient period of time for ventilation purposes before re-occupancy; such period should not be less, however, than 3 hours, during which time, the temperature of the fumigated premises should be sufficiently high to assure the complete dispersion of gases; in cold weather, the fumigated premises should be thoroughly heated as part of the ventilation operation.

Hence, to prevent stratification of gases in the northern climate, when fumigations are performed on cold days, the temperature of the fumigated rooms should not be below certain limits; this precaution is considered essential, as is also the necessary increase in the period of ventilation on muggy and humid days in the other seasons of the year.

The period of ventilation stipulated above, has been fixed after a careful study and consideration of valuable information on this subject, especially from publications of the U. S. Public Health Service and the U. S. Department of Agriculture reports, etc.¹⁷

As a matter of precaution no fumigation should be performed unless atmospheric conditions are favorable.

No attempt has been made to regulate the class of materials to be employed in commercial or industrial establishments using special fumigation chambers or vaults nor solely in their own premises nor with reference to the material contained therein. The sale of fumigants to persons other than licensed fumigators, is, however, regulated. Moreover, a report of analysis, signed by a recognized chemist, of the substances used for fumigation is required; at any time, when deemed advisable, the Health Department may cause these substances to be analyzed at the expense of the master-fumigator.

The use of fumigants in inhabited buildings has been the main object of the enacted regulations. Although hydrocyanic acid in any form is the substance intended to be regulated, other substances as well emitting or liberating dangerous gas or gases, fumes or vapors, may be considered as a fumigant and in this connection the Director of the Health Department has discretionary power.

CONCLUSIONS

The above considerations represent our well considered opinion, as sani-

tarians, reached after a careful study of the available data and expert opinions on fumigation. We admit that the greatest danger in household fumigation operations lies in the non-regulation of these activities, but we recognize, as well, that HCN and its compounds are poisonous and can cause death in a very short time, if breathed in concentrations used in fumigation work. A certain number of deaths have been recorded in the last few years when straight HCN has been used. To guard the public against carelessness and even apathy, reasonable safety measures must be provided, such as warning elements, whenever HCN is used. Cyanogen chloride has been found to give non-equivocal warning of the presence of HCN, by rendering the stay unbearable in or about fumigated premises.

Moreover, no known serious accident can be attributed to the use of HCN-CNCl mixture, notwithstanding the scientifically sound, but disputed arguments, as to the separation of its chemical constituents, under certain conditions of use.

Industrial and ship fumigation, as well as fumigations in well constructed and operated vaults or chambers, do not introduce the same hazards, and for this reason important concessions can be made to the choice of materials and the application of methods recommended for such purposes.

A great deal of effort and time have been spent by sanitary officials of different cities and by the manufacturing chemists to devise means that will safeguard human life, but no consensus of opinion has yet been reached. The supreme arbiter in all matters related to public health and sanitation in America is, without doubt, the United States Public Health Service, and, it is a great satisfaction to know that this service is taking an active interest in this question.

DISCUSSION

C. L. WILLIAMS, M.D.

Senior Surgeon, U. S. Public Health Service, New Orleans, La.

IN 1930, Dr. W. Deckert, of Hamburg, published an extensive paper on the legislative principles of the control of noxious animals by hydrocyanic acid as applied in most of the civilized countries. In this paper, Dr. Deckert endeavored to summarize fumigation control legislation as it then existed, and he cited a considerable list of laws, ordinances, edicts, proscriptions, letters of instruction, and other pronouncements. All through his paper he comments upon the confused picture presented by the continual and active change in fumigation regulations. So impressed was he by this active change that he found it necessary to tabulate control measures as they existed on a certain day, for this purpose selecting September 1, 1929.

The confusion of the picture can best be illustrated in his own words; for instance, where he says: "It appears strange when, as is sometimes the case, one country prescribes exactly what another forbids." As illustrations of this remark he cites that, in Denmark, fumigation of ships below decks is for-

bidden on account of difficulties in ventilation, whereas, in Spain, below decks may be fumigated and released after only 1 hour's ventilation, but rooms above decks must be ventilated for 8 hours. And again, in one American city, it is permissible to empty residue from fumigating crocks into the sewers, whereas, in Norway, it is prescribed that residues must be made innocuous chemically, and even then must not be poured into sewers but must be buried. Further, in Belgium, injections of camphor are prescribed as antidotes for HCN poisoning in cases of fumigation accidents, whereas, in England, the use of camphor is expressly forbidden.

So amazing and remarkable are the confusion and contradiction of directions concerning fumigation which appear throughout the paper that one with a sense of humor cannot read it without a constant smile, if not, indeed, without breaking into laughter, until, perhaps, he suddenly realizes that these variegated attempts to control as practised by the different countries of the world

are more or less exactly repeated by the equally variegated attempts put forth in the various states and in communities within the states in his own country.

It doubtless appears strange to start a discussion of one paper by discussing another, and that one of several years' standing. But, as a matter of fact, it is quite apropos. One of these papers sets forth the general confusion as concerns fumigation control; the other one, that I am specifically to discuss, sets forth some of the points on which divergence and confusion have arisen. Both of them point the way to the present need, which is a well thought out, well constructed, effective, uniform law that may be adopted, certainly in its essential provisions, in all communities. The time to construct such a model law or ordinance is now, before the innumerable communities of this continent have each, severally and separately, adopted their own more or less, frequently less, effective control measures.

The paper of Mr. Cousineau and Mr. Legg deserves particular notice because it is the first paper in this country, so far as I know, to take up definitely, in a careful and well considered manner, the subject of municipal control of commercial fumigation. The paper is an excellent one and goes so thoroughly into the difficulties in the way of setting up adequate control of fumigation that these are brought clearly to view and naturally present themselves to further discussion. They present some of the points at controversy which must be settled in order to build up a model law that may be confidently adopted throughout the country.

First, there is the matter of cost. As these writers have stated, the question is one of cost as balanced against safety. What this means in setting up control legislation no experienced health officer need be told. To the fumigator higher

costs mean less business and smaller profits; he will fight to protect his personal interest. Further, the fact that the business of fumigation, though relatively new, has already assumed considerable proportions and is rapidly growing, will tend to increase the opposition to control involving higher costs. That control does involve higher costs not only of material, but of the trained labor to whom the handling of fumigants must be restricted, is obvious.

The point made by the writers that fumigation is bound up with extermination is an interesting example of the economic association of separate (though allied) trades. At present, the great majority of commercial fumigators are also exterminators, and they are today bending considerable effort to insure that any control legislation shall include both fumigation and extermination.

Next we come to a different type of divergence of opinion—that is, the question of warning gas. Whereas the divergence of opinion concerning costs rests between administrative officials on one side, and the fumigators, and to some extent the public, on the other, the use of warning gas presents a divergence of opinion among fumigation experts and, to some extent, administrative officials themselves. Fumigators also object to warning gases, first, on the ground of increased cost, and, second, on the ground of inconvenience, the use of warning gases constituting a considerable nuisance in the handling of fumigants. To go into a discussion of warning gases here would be time consuming and would hardly serve a good purpose. As one thoroughly familiar with the subject, however, it is my opinion that the controversy over them will not be settled until a new gas is developed that reasonably approaches hydrocyanic acid in efficiency and is in itself a warning gas. A great deal of the present difficulty over warning gases is

that they are gases added to the fumigant.

A third major point of controversy that lies in the way of uniform fumigation control legislation is the proposal to require fumigators to establish their financial ability to cover damages, in the form, usually suggested, of a liability insurance policy or a liability bond. The point at issue here is that only firms of unusually good standing can secure such insurance policies or bonds. This, of course, is the principal aim. Practically, it is an excellent method of securing competency among fumigators, but it may be open to question whether it is altogether proper to enlist, for fumigation control purposes, the services of insurance and bonding companies. The interesting point in regard to this feature is that on the surface it appears that it would be far more effective than other means in immediately improving the type of personnel engaged in fumigations. Insurance companies would probably be much more careful as to whom they granted insurance policies than would be political bodies in issuing fumigation permits.

As to the present need for fumigation control, it is not immediately urgent. Deaths from this cause are probably between 10 and 20 a year in the United States, this of course constituting a trifling figure compared to almost any other cause of death. Fumigation, however, is steadily increasing and this figure may be expected to become greater rather than to be reduced in the immediate future. Furthermore, deaths from fumigation are spectacular and are generally widely published. Nearly all of them, as has been pointed out in this paper, are due in the last analysis to some one's carelessness or negligence.

The great majority of accidents during fumigation of inhabited buildings come under four headings:

1. Accidents to fumigators—These are due to pure downright carelessness or ignorance and can generally be traced, in the final analysis, to improper training of the fumigator or lack of discipline by the man in control.

2. Retention of gas in bedding and other upholstered furniture, with its subsequent release after the compartment has been closed. This is the most prolific cause of deaths in the fumigation of homes, and again, in the last analysis, may be ascribed to carelessness or ignorance. At present writing, I am inclined to believe they may be due more to ignorance than carelessness, as I am convinced that the majority of the fumigators are not really aware of the considerable amounts of hydrocyanic acid gas that are absorbed by bedding, nor of the demonstrated fact that it is released relatively slowly, particularly at low temperatures. Incidentally, this is the type of accident in which present-day warning gases generally fail.

3. Entrance into building under fumigation—This type of accident is due either to failure to place guards, or to failure of guards to perform their duties. Punishment of those responsible for this type of accident should be severe.

4. Passage of gas from one building to another through unsuspected openings—This type sometimes approaches nearest to a genuine accident, as the connections may be most obscure. When the gas passes through plumbing conduits, however, only the fumigator is to blame.

In closing, I feel that I should state my belief as to the form in which a fumigation control law should be drafted. The opening statements of this discussion stressed the state of confusion and rapid change in fumigation control. Obviously, to meet such a situation requires a reasonable variable and flexible law, so that I plead for one in which the essential authority and the policy foundations are set forth in the act, but in which, also, provision is made for details of control to be covered by regulations which may be amended (within the act) by the administrative authority.

DISCUSSION (*Cont.*)

F. S. PRATT

Vice-President, Pacific R. & H. Chemical Corp., El Monte, Calif.

ON November 16, 1930, a well known furniture store in uptown New York City was fumigated by the cyanogen chloride method as advocated in the paper which has just been read. Next door, separated from the furniture establishment by a partition wall was a restaurant. Before the fumigation was completed, 15 people in the restaurant were overcome and 5 of them required hospital treatment.

On the morning of December 12, 1932, a steamship in the harbor of Seattle, Wash., was fumigated by this same method. In the early afternoon the ship was opened and ventilated and passed as clear about 4 o'clock. A member of the crew who came aboard and went to bed about 7 o'clock that evening, was found dead in his berth the next morning.

On the evening of December 31, last, a fishing schooner tied up in the harbor of Gloucester, Mass., was fumigated by this same method. During the evening of the same day a sailor came aboard, opened the companionway and entered the crew's quarters. His dead body was found there the next morning when the boat was opened and ventilated.

In view of these three accidents, the statement of the authors that "no known serious accident can be attributed to the use of HCN-CNCl mixture" must be regarded as incorrect.

While I am impressed by the persuasiveness of the arguments which have been so ably presented by them, I find that they all rest upon this assumption, namely, that if a tear gas is added to a fumigant, the resulting mixture will retain its warning properties through the fumigation period and until ventilation is complete. It seems to me that the fallacy of that assumption is clearly demonstrated by the three cases which

I have cited, the circumstances of which can be easily verified by anyone who chooses.

It has been remarked by Dr. Edward Bocker, a distinguished expert of the Department of Health of New York City, that "unless a warning gas is wholly satisfactory, it is not satisfactory at all"; if a particular warning agent cannot be relied upon every time, it should not be relied upon at all. "Like the safety belt of the window washer, unless it is reliable every time, he is better off without it, otherwise a false sense of security is created which will ultimately result in disaster." Similar views have also been expressed by Dr. J. T. Oberweger, Superintendent of the Division of Sanitation of the New York Board of Health.

As you know, it is necessary for all fumigation operators to be provided with effective gas masks and to wear them constantly whenever they enter a space under fumigation. Whenever the circumstances are such that an operator is compelled to wear his gas mask, his life may depend, and usually does depend, upon the effectiveness of his gas mask, and that of the operator who should go with him. If, as the authors of this paper recommend, a powerful tear gas is added to the fumigant, the gas mask is thereby called upon to perform an additional, and in some respects, more difficult task, for if the tear gas gets to the man's eyes, either through the canister or through a pin hole in the rubber face piece, the man will be blinded and cannot possibly find his way out alive unless someone leads or drags him out. Accidents have been reported—some of them fatal—the circumstances of which fit this explanation.

If I may be permitted to interpose at

this point a few personal remarks to indicate the reason for our interest in the subject matter of this paper, I would like to say that the concern with which Mr. Ressler and I are connected manufactures and sells a considerable number of materials other than cyanide for use in pest control by fumigation and otherwise. All pest control fumigants, properly so called, are toxic to human beings as well as insects. Some are less toxic than others but *when used in a concentration great enough to be effective in insect control, all of them are potentially dangerous to human life.* Everyone, therefore, who deals with the field of domestic fumigation must consider with great care the matter of public safety. We, as manufacturers, regard that obligation as one of profound importance as compared with which any profit which may be gained from the sale of fumigant materials is a matter of distinctly minor importance. We hold no brief against cyanogen chloride as such. On the contrary, those who make and sell it are our customers. They buy our materials, and, while the entire quantity of cyanide which we sell for domestic fumigation is but an infinitesimal part of our total sales, the general adoption of cyanogen chloride would tend to increase rather than decrease our sales volume.

I desire thus to make clear to you the point of view from which we approach the subject matter of this paper because it might be inferred by some that the reason why we disagree with the authors is because we fear that their suggestions if generally adopted would be prejudicial to our financial interest. Nothing could be more incorrect. We disagree because, after very careful study, we are convinced that the plan which the authors recommend is dangerous to human life.

The idea of using tear gases in connection with fumigation is not new. Beginning about 15 years ago, the U. S.

Public Health Service sought suitable tear gases for use in conjunction with hydrocyanic acid. These investigations resulted in the adoption of cyanogen chloride, and attention was called to this fact in amendment No. 6 to the quarantine regulations issued by the Service in 1923. Shortly after, the Service discontinued the use of cyanogen chloride in favor of chloropicrin. More than 5 years subsequent to the abandonment by the Service of the cyanogen chloride method, an eastern corporation which had undertaken the commercial exploitation of cyanogen chloride fumigation gave wide publicity to the subject matter of the 1923 bulletin in such a manner as to make it appear that the U. S. Public Health Service favors the cyanogen chloride method above all others.

In 1930 and 1931 the Bureau of Mines, in coöperation with the U. S. Public Health Service, conducted an investigation which had for its object the finding of a warning agent which could be incorporated into artificial or natural gas sold for domestic use with the expectation that if a warning agent could be found appropriate for this purpose, its use would cut down the number of deaths which are due to accidental asphyxiation. It is reported that in this investigation hundreds of compounds were exhaustively studied at a cost of more than \$20,000 without finding any which were deemed satisfactory.

It is a matter of common knowledge that deaths due to illuminating gas are far more frequent than those caused by fumigations. This fact has been recently confirmed by an investigation of Major C. L. Williams, Senior Surgeon of the Public Health Service. The results of his investigation, which were published a few weeks ago, show that during the 6 months period covered by his study, the number of deaths in the United States caused by fumigation were less than one-quarter of those

caused by illuminating gas and less than 2 per cent of those resulting from the inhalation of all other poisonous gases. Deaths from illuminating gas, therefore, represent a far more important problem of public safety than the hazards arising out of fumigation. Notwithstanding this, the warning gas idea has not yet impressed government officials and others familiar with the facts to the point where warning gases have been adopted in the gas industry. In that industry, the relevant facts have been studied with great care in the investigation to which I have referred (*Bureau of Mines monograph No. 4*, entitled "Warning Agents for Fuel Gases").

It seems appropriate therefore to suggest that before sponsoring the enactment of mandatory legislation which would require the use of a particular warning agent in fumigation, health officers would be wise to insist upon a really careful factual case study of all known fumigation accidents to determine in each instance the cause and what individual or individuals were responsible.

It is, nevertheless, no secret what must be done in order to deal successfully with the hazards of fumigation. There are only two basic requirements. First, the practice of fumigation must be confined, by means of a suitable permit system, to individuals who possess the proper qualifications of training, experience and character; and second, those individuals must be held accountable for the performance of fumigations in accordance with safe practices that are already well recognized. The successful enforcement of such requirements no doubt brings to the health enforcement officer some administrative problems. How serious these problems are I do not know, but however troublesome they may be, it is clear that the vast majority of our cities are handling them successfully today.

In the paper which has just been

read, it is stated that "in accordance with the carefully considered policy of the Health Department of the City of Boston where the above fumigants (cyanogen chloride) have been mainly used, no attempt to regulate fumigation has ever been made." It is not clear to me just what the authors wish to be understood by that statement unless they wish to be understood that wherever cyanogen chloride is used as a warning agent, one may safely relax some of the precautions which would otherwise be necessary. Similar claims have in the past been made by individuals interested in the commercial exploitation of this method of fumigation. Any such suggestion is not warranted by the past record of fumigation in which cyanogen chloride has been used. In the handling of dangerous materials I am prepared to state emphatically that there is no substitute for training, experience, care, and vigilance. I make this assertion on the strength of 15 years' experience during which several thousand tons of hydrocyanic acid has been manufactured and shipped under my personal supervision without a single fatality.

Before I conclude my remarks I should like to quote from two paragraphs of the article by Major Williams to which I have already referred:

During the 6 month survey, the number of deaths reported in the press clippings reviewed which occurred from fumigant gases in the United States totaled 6, while deaths resulting from the inhalation of other poisonous gases numbered for the same period 382.

According to information obtained from available sources, it is estimated that the number of building, railway, and ship fumigations performed in the United States during 1933 was approximately 74,000. Of this number about 60,000 were fumigations of domestic dwellings, 5,000 industrial fumigations, 7,000 railway cars, and 2,000 ships. In addition to these, there are performed yearly a large number of horticultural fumigations, for which it is difficult to arrive at a definite estimate owing to the fact that these fumigations are figured in "acres of glass." There are about

15,000 greenhouse companies in the United States, many of which own long ranges of greenhouses. Greenhouses fumigate at least once every month during the growing season, and mushroom houses several times during the year. The year 1933 having been a subnormal year, the estimates cited above may be considered conservative. From these figures it would appear that the deaths average about 1 to every 6,000 fumigations. . . .

Notwithstanding the relatively small number of fatalities at present occurring from this cause, nevertheless in view of the trend toward increased use of lethal gases for domestic purposes, the adoption of reasonable legislation

for the control of the practice is believed advisable; but at present it is apparently not a matter of justifying emergency or ill-considered enactments.

In conclusion and in view of the known record, I want to say with all the earnestness at my command, that any body which enacts legislation relying on this so-called warning agent for the protection of human life or any public officer who sponsors such legislation, takes upon himself a fearful responsibility.

REPLY TO MR. PRATT'S DISCUSSION

AIMÉ COUSINEAU AND F. G. LEGG

THE discussion of our joint paper by F. S. Pratt, Vice-President of the Pacific R. & H. Chemical Corporation, El Monte, Calif., was not officially listed on the program. In some respects its presentation was a surprise to the authors; on the other hand, we have known for a number of years that the cyanide manufacturers have been opposed to the use of warning gases unless the "perfect warning agent" which will prove effective under any and all conditions, is perfected. We naturally respect their opinions and, although we cannot agree with their conclusions, we welcome Mr. Pratt's discussion and urge its inclusion as a contribution to a subject that is of vital concern to those interested in public safety. The object of any paper is to invite discussion. The more voluminous the comments, either pro or con, the more valuable in proportion will be the contribution to the subject at hand.

Any person or persons sponsoring the enactment of legislation reasonably calculated to afford greater protection to the public, if he or they be sincere, need not be unduly perturbed by the conclusion presented by Mr. Pratt "that any body which enacts legislation rely-

ing upon this so-called warning agent for the protection of human life, or any public officer who sponsors such legislations, takes upon himself a fearful responsibility."

In the last analysis, the public expects, and justly so, that some public minded person or persons will be solicitous for their welfare and will do everything within reason to protect their interests. Mistakes may be made, but efforts in the anticipation of increased safety are justifiable, and any attempt to minimize in any way an existing hazard that cannot be denied appears reasonable.

The authors have not admitted that warning gases, as now used or recommended, are perfect. Our statement in this respect is clear in that we believe that the objections to their use are not serious enough to outweigh the advantages of their use, provided that all known precautions are taken as well.

The citation, of the three accidents, by Mr. Pratt as having occurred where warning agents were employed is not, in our judgment, a sufficient ground for a blanket condemnation of the use of warning agents.

The New York accident mentioned by

Mr. Pratt did not result in any fatality. Had other known precautions been observed, as are recommended by the authors, even with the use of warning agents, the accident might possibly have been prevented. New York does not require warning gases to be employed in fumigation, and because it is alleged that a warning gas was used in this particular instance, and that it did not prove to be 100 per cent effective, is no conclusive proof that warning gases have no value in fumigation. There is the possibility that the warning agent in the instance cited may have had some value in preventing more disastrous results.

At the time our paper was prepared the authors were not in possession of the facts relating to the two cases cited in which the use of warning gases resulted in fatalities in Seattle and Gloucester. We have not, as yet, been able to obtain the official reports of these accidents.

The one in Seattle, we understand, was on shipboard and probably outside of the jurisdiction of the Seattle Health Department as we have reason to believe that the Seattle Health Department did not have complete details at that time. The one in Gloucester was also on shipboard and possibly outside of the jurisdiction of the local health department.

According to our information this last fumigation had been made without the services of a fumigating company, and the most elementary precautions, such as the services of a watchman, who, no doubt, would have prevented the victim from going down the fore-castle of the ship to reach his bunk, after a tiresome day or leave of absence.

It is not our purpose to deny the occurrence of the three instances cited by Mr. Pratt. It is, however, our purpose to assert that if other known precautions had been employed in connection with these fumigations, the mere fact that a warning agent was employed is not in our judgment sufficient proof of the undesirability of warning agents in fumigating practices.

The statement by Mr. Pratt which has reference to the number of deaths caused by illuminating gases as being 4 times those caused by gases used for fumigating and exterminating should be carefully analyzed before any conclusions should be drawn from the statement. It is probably true that a relatively large percentage of all homes in urban communities are provided with illuminating gas services for cooking and for water heaters. Those who have experience in the control of cyanide gas fumigation would, I am sure, have many sleepless nights if fumigation were to be performed over a period of 6 months in every dwelling in the country in which there is a service for gas.

The Part of the Public Health Nurse in the Epidemiology of Syphilis*

Maternity and Child Health Services

HELEN S. HARTLEY

Superintendent of Nurses, San Joaquin Local Health District, Stockton, Calif.

THE relation of the public health nurse to maternity and child health services has long been considered of importance. The interpretation of the part of the public health nurse in the epidemiology of syphilis presupposes that she is one who:

Is prepared or experienced in general public health activities

Recognizes syphilis as a communicable disease

Knows the facts of diagnosis, treatment and communicability of the disease

Appreciates the pathological, social and economic importance of early diagnosis and treatment

Understands that her approach to the syphilitic patient is comparable to that of any other communicable disease

Is acquainted with community agencies and institutions offering diagnostic and treatment services.

It is also assumed that a community employing public health nurses is cognizant of the social and economic importance of preventive as well as curative services, and that some provision is made for them.

The effectiveness of the public health nurse's work is directly influenced by the services provided within the community which limit or increase her op-

portunities for usefulness. Her assistance may be given to patients of private physicians or as part of a free or pay clinic service. Her procedure will be in harmony with the program of treatment of the patient by the physician in office or clinic practice, and her first duty is to know that program.

The home visit gives opportunity for interpretations of many procedures that are quite clear and simple to a member of the profession, but vague to the patient and family. There the nurse finds the best opportunity to stress the importance of medical supervision early in pregnancy and teaches the value of each step. Even though the physician may have explained the meaning of a positive Wassermann and need for treatment, there will be lingering fears or questions needing to be cleared away. Encouragement may be necessary for the patient to continue treatments. Changes in the family régime may be required, and with the aid of the experienced worker, a schedule may be evolved whereby the wage earner's time may be less affected and add to the convenience of the patient and other members of the family.

Transportation is an important factor for the prenatal patient who must also attend the anti-luetic clinic. It is comparatively easy for volunteer transportation to be secured for an occasional

* Read at a Joint Session of the American Social Hygiene Association and the Public Health Nursing Section of the American Public Health Association at the Sixty-third Annual Meeting in Pasadena, Calif., September 3, 1934.

visit, but to continue these visits at regular intervals over a long period of time adds complications. However, that such a program can be effected was demonstrated by a member of a volunteer motor corps who left her home before 8 o'clock to bring a mother and her 4 small children to the morning anti-luetic clinic. The time involved was approximately 3 hours, the distance approximately 15 miles, and the volunteer carried on without omission for the entire series of treatments.

Responsibility for the continuation of the mother's treatment after the post-partum period often rests with the nurse. As in any other long continued treatment, there is a tendency to grow lax, and it again becomes necessary to emphasize the need and make new plans for the care of mother and child over prolonged and repeated periods.

A principle applied to all communicable disease control is that requiring examination of contacts. Certainly no public health nurse will fail to bend every effort to secure adequate examination of contacts of a luetic patient although it may present some difficult, and sometimes delicate, situations.

The triangle relationship of clinic, patient, and public health nurse should not be ignored. Of course, the anti-luetic clinic is of prime importance but many of its patients are recruited from other clinics and in proportion to the thoroughness of examinations and system of reporting. The routine of clinic activities offers many opportunities for correlation of programs.

Since syphilis may be passed from mother to child in utero, the prenatal clinic holds a definite place in the control and prevention of syphilis. The patient should be urged to register early in pregnancy and the Wassermann should be part of the routine procedure of the first visit. In one prenatal clinic, all new registrants' names, addresses, and probable dates of maturity are

given to the health department for the prenatal teaching program. The clinic registrar reports to field nurses all positive Wassermanns, and the patient is immediately referred to the anti-luetic clinic for treatment. Patients registered in this prenatal clinic are confined in the hospital where spinal fluid Wassermanns are a routine procedure.

Routine duties of the obstetrical ward include a report to the health department of patients dismissed with address, age, and condition of infant, condition of mother, and special note of lues or other symptom requiring attention. These reports are referred to the public health nurse in whose district the patient resides, and home visits are resumed.

Upon dismissal from the hospital, each mother is given dates for post-partum visits to the clinic. When the mother is dismissed from post-partum care, the baby is transferred to the well baby clinic for supervision throughout infancy and preschool life. In the well baby clinics, observation for control of luetic infections is continued.

Study of 583 maternity patients from this clinic and hospital service in 1 year resulted in finding 10 mothers with positive luetic reaction. Each patient was given at least 2 tests. Reaction of 1.7 per cent is a very low incidence in a highly cosmopolitan clinic group as compared with reports from other parts of the country. In a children's clinic of another California city, also highly cosmopolitan, records of 3 years show 2 per cent of all children registered had congenital syphilis. Since treatment for congenital syphilis is recommended to begin in infancy, the emphasis of the public health nurse may well be upon the care of the very young child.

However, we are told the prevention of congenital syphilis depends upon treatment of the infected mother from the third month of pregnancy until the

infant is born. Here is a definite challenge to the public health nurse to secure adequate prenatal care for each and every woman whether she be the patient of clinic service or of private physician.

Two types of clinics cover supervision and care in child growth and development—supervisory and treatment. Both offer opportunities for diagnosis. Supervisory clinics may be conducted by health departments conforming to recognized public health principles. Treatment clinics, pay or free, constitute the medical relief service for definitely sick children, some of whom may have symptoms directly traceable to luetic origin. Possibly the supervisory clinics deal with children having more obscure symptoms which may respond to treatment.

Many problems arise in correlation of health and social programs from the clinics offering:

Examinations for school children

Examination of families applying for state aid

Examination of children admitted to children's home

Examination of children referred to institutions for correction of social adjustment

Problems may be a challenge to the policies of organizations serving the

people in clinical diagnosis and treatment, material relief, preventive health and educational service. That relief agencies recognize the value of prevention and follow recognition with action is demonstrated by the solution of a problem arising from the examination of a mother applying for state aid. Anti-luetic treatments were needed and the most convenient means of transportation was by interurban railway. The relief agency paid the carfare which amounted to about \$.90 round trip, and felt justified in doing so because of the improved health of the mother.

There are many factors and many workers concerned in the process of correlating programs in the evolution of adequate health and welfare facilities, but given the vision, the public health nurse may play an important rôle, for hers is the opportunity to:

Teach individuals and families to protect their own health and safeguard the health of their children.

Encourage and assist in the adjustment of individual, family and social conditions that effect the health program.

Join with other health and social workers in correlating programs for the welfare of the individual and the community.

Respond to the challenge and assist in the control and prevention of syphilis through public health nursing activities connected with maternity and child health services.

Fish and Sea Food Institute of the United States

ESTABLISHMENT of the Fish and Sea Food Institute of the United States, with headquarters at 80 Broadway, New York, N. Y., is announced. It is "sponsored by the fish industry to promote a better understanding of the advantages of fish and sea food, emphasizing its economy, food value, and taste." At an inaugural luncheon on February 5, attended by dietary experts, health officials, home economists, research experts and others whose in-

terests are increasing the per capita consumption of fish, the speakers included: Harden F. Taylor, a director of the Fish and Sea Food Institute of the United States; William Fellowes Morgan, Jr., Commissioner, Department of Markets, Weights and Measures, City of New York; Agnes I. Webster, home economist, U. S. Bureau of Fisheries; and J. George Frederick, president, Society for the Advancement of Better Living.

Some Observations on the Use of Alum Precipitated Diphtheria Toxoid*

W. T. HARRISON, M.D.

*Surgeon, U. S. Public Health Service, National Institute of Health,
Washington, D. C.*

SINCE Glenny and Barr,¹ in 1931, first described a method for the precipitation of diphtheria toxoid with potassium aluminum sulphate and showed its exceptional antigenic efficiency in animals, evidence has been rapidly accumulating that a single dose will change well over 90 per cent of Schick positive children to Schick negative in 8 weeks. Wells, Graham, and Havens,² in 1932, confirmed the observations of Glenny and Barr in guinea pigs and gave the single dose injection to 98 children, all with strongly positive Schick reactions. At the end of 8 weeks all but 6 had been rendered Schick negative. Graham, Murphree, and Gill³ obtained more than 92 per cent negative Schick reactions in 185 Schick positive children, within 2 to 4 months after a single injection. Baker and Gill⁴ in 197 Schick positive children (22 of whom were older than 13 years) obtained negative Schick reactions in 100 per cent after a single dose. McGinnis and Stebbins,⁵ using 1 dose of precipitated toxoid and working with a representative number of children, all of whom were Schick tested before and after immunization, concluded that—

One dose of alum precipitated toxoid is as effective as 2 doses of toxoid containing 10 units with 0.2 per cent alum added.

They obtained with 2 doses of toxoid containing 0.2 per cent alum and 1 dose of alum precipitated toxoid, 95.4 and 95.9 per cent Schick negatives, respectively, in 295 and 266 children in the age group 5 to 9 years. Thus there does not seem to be any question as to the efficiency of alum precipitated toxoid as an antigen—it is without doubt the most effective agent yet devised for immunization against diphtheria, but it has certain distinct disadvantages which will be mentioned later.

Most workers have indicated that the probable reason for the extraordinary activity of precipitated toxoid lies in the slow rate of absorption of the comparatively insoluble precipitate, the single injection acting as both the primary and secondary stimulus defined by Glenny and Sudmersen.⁶ To test this theory, an experiment was planned wherein the nodule which persists at the site of injection was dissected from the tissues of guinea pigs at weekly intervals, and reinjected into guinea pigs in which the serum had previously been titrated at the 1/250 unit level to insure the absence of antitoxin. Nodules were dissected from 2 to 4 pigs each week up to the 7th, ground in a mortar with salt solution, and reinjected into

* Read at a Special Session on Diphtheria Immunization of the American Public Health Association at the Sixty-third Annual Meeting in Pasadena, Calif., September 4, 1934.

2 test pigs. These test pigs were bled after 6 weeks, the serum of each pair pooled and tested for antitoxin. Antitoxin was present in the serum of all, those reinjected at the 7th week showing $1/5$ unit per c.c. Thus it is apparent that 1 dose in the tissues of the guinea pig exerts its antigenic effect for at least 7 weeks. Since induration following injection in children may be elicited for as long as 6 to 8 weeks, it seems reasonable to assume that the stimulation of antitoxin production continues for this period.

This long continued antigenic action not only serves as a constant stimulant to the mechanism of antitoxin production but also seems to produce in a few persons hypersensitiveness to the protein contained in a subsequent Schick test. McGinnes⁷ has reported a number of immediate allergic reactions following the Schick test applied 8 weeks after precipitated toxoid, in at least one of which adrenalin was required. Preliminary Schick test in the same children was not followed by unusual reaction. The writer⁸ has described the antigenic action of alum precipitated pollen extract as compared to liquid extract in the guinea pig and has shown that the precipitated extract is a much better sensitizing agent than the same extract before precipitation. It is probable that the explanation for the allergic reactions observed by McGinnes lies in this increased sensitizing action of the precipitated toxoid over the fluid toxoid from which it was prepared. It is of considerable interest that the same immunizing procedure is so highly effective in the production of both antitoxic immunity and protein hypersensitiveness.

In a small number of observations it has been noted that vaccination against smallpox, if done as early as 11 days after injection of precipitated toxoid, may be followed by a localization of the virus around the indurated nodule.

This localization is shown by an aerola equal in size and character to that surrounding the vaccine pustule, and fades at the same time. Vaccination 21 days after injection of toxoid in 11 subjects showed normal vaccinia in 9, and in 2 there seemed a slight tendency of the virus to localize at the site of toxoid injection. Further studies on this tendency of localization of vaccine virus should be made, the site of toxoid injection being carefully examined from the 9th to the 12th day after vaccination. Simultaneous immunizations offer an excellent opportunity for study of these reactions.

The immediate local or general reactions following precipitated toxoid are no more noticeable than those following crude toxoid. Most workers believe that they are less so. The very slow rate of absorption as evidenced by the persistence of an indurated nodule at the site of injection should decrease the allergic reaction due to hypersensitiveness to diphtheria protein. Toxins intended for the preparation of precipitated toxoid should be grown for as short a period as is consistent with the production of a strong toxin in order that the concentration of autolytic products may be kept as low as possible. Good toxins may be produced in 7 to 8 days; and longer cultivation, while increasing flocculating value, probably adds materially to the number and severity of reactions in sensitive subjects.

During the past few months an increasing number of reports of the occurrence of sterile abscesses following precipitated toxoid have been received. These develop in from 6 to 10 days after injection, are very slightly painful, sterile, and heal readily after incision. Some may open spontaneously while many indurated areas develop small points of fluctuation which go on to resolution without surgical interference. To date, all products reported as hav-

ing caused abscesses have either been manufactured from toxins grown for longer periods than 8 days or have contained an excess of aluminum, or both factors have been found to be present. Manifestly, the injection into the tissues of a comparatively insoluble precipitate will of itself set up some degree of local irritation, and any additional irritating factor will necessarily add to the probability of abscess formation, hence the necessity for keeping the content of aluminum and of bacillary protein at the lowest possible figures. While approximately 1.5 per cent potassium alum which is present in toxoids precipitated with 2 per cent alum seems to cause a degree of induration which is not particularly objectionable, the preparation of toxoids which require less alum for precipitation, reducing the aluminum to a still lower percentage, will represent a distinct improvement in the product. The possibility of a very slight residual toxicity in crude toxoids from which the precipitates are prepared must also be considered. Such toxicity would necessarily be so slight as to escape detection by the routine 5 c.c. doses in guinea pigs observed for 30 days, but might conceivably be sufficient to produce unpleasant reactions during the extended period that the precipitate is in contact with the tissues. This point is being further investigated.

Children under 6 years give a minimum of local and practically no general reactions to precipitated toxoid, and since a large proportion of this age group is susceptible to diphtheria, they may be immunized without prior Schick test. Older children, however, in addition to furnishing a lower percentage of susceptibles are more prone to show un-

pleasant reactions and therefore only susceptibles should be injected. Precipitated toxoid is so dependable in its antigenic activity that for practical purposes in mass immunization, a post-Schick test may be omitted, not more than 5 or 6 per cent of children who receive a single dose showing a positive Schick after 8 weeks. The post-Schick test is more difficult to interpret after precipitated toxoid, probably due to increased sensitivity to the protein in the Schick material which is induced by the long continued stimulation during the immunizing process. A heated control is necessary to avoid confusion in doubtful cases.

The enormous advantage of immunization by a single injection needs no comment and the rapidity with which precipitated toxoid is supplanting the older agents is evidence of its popularity with the profession. However, the objection of unpleasant reactions must be kept in mind. There is increasing evidence that these reactions, frequently resulting in abscess formation, are more common than reports indicate, and in order that the product may be steadily improved, field experiences should be reported to central authorities for transmission to the manufacturers.

Home Canning and Public Health^{*}

FRED W. TANNER, F.A.P.H.A.

Department of Bacteriology, University of Illinois, Urbana, Ill.

THE art of food preservation by canning in the factory has never been on a sounder basis than it is today. Hundreds of thousands of dollars have been spent to bring the industry to its present position. Spoilage has been greatly reduced and no outbreaks of botulism have been attributed to factory-canned foods packed in America since 1925. This statement becomes still more significant when the relatively small amounts of home-canned foods in contrast to the large amounts of factory-canned foods are considered. The situation for home-canned foods, however, is not so fortunate. Procedures are still recommended to the home-maker which not only give products which may not keep well but which may poison her entire family. Frequent warnings have been given of the danger of inadequate processes. Schoenholz, Esty, and Meyer¹ warned that home-canned foods may be dangerous when they said:

The prevention of human botulism will, therefore, remain a difficult problem until safe processing procedures are employed in the household for the preservation of certain vegetables.

This opinion has been borne out by large yearly tolls of botulism caused by home-canned foods since then. Fellers² made the following statement:

The canning guides, bulletins, circulars, and recipes distributed by state agencies, maga-

zines, women's clubs, and manufacturers of canning equipment contain many erroneous statements and faulty methods which have been directly responsible for several outbreaks of botulism besides causing great losses through spoilage of good human food. Accurate and safe directions for preserving food products should be prepared by state colleges and similar agencies in order that any present faulty, unsafe methods may be rectified.

A similar warning was issued by the California State Department of Health in 1933.³ Despite these emphatic statements, little attention seems to have been given to the problem by some of those who are advising home-makers, and botulism outbreaks caused by improperly processed home-canned foods continue.

Any method of food preservation may be evaluated largely from two positions—spoilage and food poisoning. The former has been almost entirely ignored by some of those who disseminate information to the home-canner. Little actual information is available, however, on spoilage, for the average home-maker keeps no records. Neither is she trained to detect all kinds of spoilage, and undoubtedly many home-canned foods which have started to spoil, are prepared for the table because evidences of spoilage are not sufficiently pronounced. Although this phase of the problem need not be stressed unduly before this Association, spoilage is closely related to poisoning. A preserved food in which considerable spoilage has taken place may be potentially dangerous. *Clostridium botulinum*, the agent of poisoning of greatest

^{*} Read at a Joint Session of the Laboratory and Food and Nutrition Sections of the American Public Health Association at the Sixty-third Annual Meeting in Pasadena, Calif., September 3, 1934.

interest in this connection, may produce profound changes in the foodstuff. Foods which have undergone such changes would ordinarily be excluded from the diet. However, it is definitely known that toxin may be present without evidences of decomposition.

Few studies seem to have been made on the keeping qualities of foods preserved by methods used by the home-maker. Stienbarger⁴ summarized the results of such studies started by the Bureau of Home Economics in 1917. The period elapsing between processing and opening varied from 2 months to 5 years and averaged 1 year. In general, jars which were stored for longer times showed greatest spoilage. Containers which had imperfect closures were excluded from the summary. Bacteriological examinations were, in general, not made. cursory examination for the usual signs of spoilage (condition of the container, appearance, odor, and sometimes flavor) was the only criterion. Bacteriological examination would probably have shown higher incidence of under-sterilization. Of 3,434 jars and cans of food, most of which were processed in boiling water, 1,659, or 48 per cent, showed evidences of spoilage. Of 783 jars processed in the steam pressure cooker, 93, or 12 per cent, spoiled. Stienbarger, however, pointed out that since some of these jars had been packed, longer processing times have been found to be desirable and 12 per cent spoilage is probably much larger than would be found today. The foods most frequently spoiled were meats, fish, corn, lima beans, and peas. Meats and fish processed in the water-bath showed heavy spoilage.

The report should be read by all who are directly interested in home-canning and especially by those who still favor boiling water processes for non-acid foods. To show a few of the data reported by Stienbarger, Table I has been prepared. Spoilage, it will be seen, is

as high as 71 per cent in one food. In some cases the process times used were shorter than those recommended today, in others they were longer. Comparison of process times used with the foods in Stienbarger's report with those now recommended by some manufacturers of canning equipment indicates that they compare quite well. Sunderlin, Nelson, and Levine⁵ also reported the results of comprehensive studies in home-canning. Their work was carried out "with a view to securing spoilage data and time tables for this method of canning vegetables and meats. . . . Process times found entirely satisfactory, under the conditions of the experiments were 2½ hours for beans and chard, 3 hours for beef and pork, and 20 minutes for tomatoes."

Bacteriological tests on the jars consisted of microscopic examination of the sediment, plate count at 37 and 20° C., and growth in fermentation tubes. No attention was given to anaerobic spore-forming, or thermophilic bacteria, the organisms chiefly responsible for spoilage in canned foods. Furthermore, the majority of the jars were not incubated at 37° or 55° C. before examination. In a pack of green beans the temperatures of storage had a decided effect on the keeping qualities. No difference was observed between basement and room temperatures since no spoilage occurred after 2½ and 2 hr. boiling water processes. However, at 37° C., and 55° C., the amount of spoilage was 66 and 100 per cent respectively. They interpreted this to indicate that sterility was not obtained although products were secured which would keep if stored at sufficiently low temperatures. What would the "keeping quality" have been if all of the jars had been stored at 37° and 55° C.? They reached the conclusion that whether better results would be obtained by the use of the pressure cooker than by the boiling

water bath remained to be seen. Adequate methods of examination of the jars might have given a different picture. The possible relation of food poisoning by *Cl. botulinum* to home-canned foods was not studied. They refused, however, to taste of their foods even though the processes were said to have been satisfactory under the conditions of their experiments.

Spoilage might be considered to be of economic importance mainly and botulism of public health significance. *Cl. botulinum*, however, is a spoilage or-

such a situation will be allowed to continue remains to be seen. In some states serious outbreaks of poisoning had to occur before any real advance could be made in changing unsound recommendations. The outbreaks of botulism which have occurred in the United States for the years 1929 to 1933 inclusive are shown in Table III.* Examination of Table III should convince one that something is wrong with procedures used by home-canners, for home-canned foods are involved in practically every outbreak during these

TABLE I

ganism and any pack of non-acid home-canned foods in which there is an undue amount of spoilage may be considered to be potentially dangerous because it probably has been under-sterilized.

As stated above, not an outbreak of botulism has been caused by foods canned in American factories since 1925. This fortunate situation results from the expenditure of large sums of money to learn more about *Cl. botulinum*, heat penetration into canned foods, and other factors important in canning. The situation for canning in the home is not so satisfactory. Each year sees its toll of human lives which, to a great extent, may be credited to some extension services, editors of cookbooks, and manufacturers of supplies for the home canner. In Table II, the recommendations of a number of such authorities are given. How long

years. Stronger evidence that home-canning literature needs revision need not be sought. In the *31st Biennial Report* of the Department of Public Health of California it was stated that since 1889, 192 known cases of botulism occurred, 119 of which resulted fatally. Most of them were said to have been caused by home-canned foods. If graduates of schools of home economics and others who consider themselves capable of recommending procedures for the home-maker do not recognize all bacteriological knowledge, they should be forced to do so by those whose duty it is to conserve the public health. It would be unfortunate to have to resort to legal procedures to indicate that those who distribute unsound literature have some responsi-

bility to the public. Furthermore, those who interpret scientific data for those who are less informed, must leave nothing unsaid. Improperly processed home-canned foods are hazardous.

Canned food technologists are agreed that non-acid foods must be processed only under steam-pressure. Steam-pressure cookers have been devised for this purpose, but the mere use of such a cooker is not sufficient, for it must be correctly used and the non-technical home-maker must be taught to appreciate the necessity of following instructions which come with the cooker. Some of these instruction books should be more carefully written.

Practically all pressure cookers de-

pend on a pressure gauge alone for controlling temperature. This is probably satisfactory if the gauge is of high quality and all air is removed from the cooker. The pressure gauges furnished with some cookers are probably untrustworthy. However, good canning practice should provide for a reliable thermometer with which the actual temperature may be determined. This is necessary not only because the atmosphere in the cooker may contain considerable air, but because the gauges may become faulty by use year after year without inspection and adjustment. The effect on temperature of various amounts of air in the steam is well shown in Figure I. Stienbarger's

summary⁴ showed 12 per cent spoilage in vegetables and meats processed in the steam-pressure cooker. This would seem to indicate that more attention should be given by home economics extension advisers to recommendations for operating such cookers. The mere use of such cooker may not yield sound foods. One of the outbreaks of fowl botulism reported in 1933 resulted from home-canned food processed in a steam-pressure cooker.

Some of the advice given the home-

maker on the operation of the pressure cooker is quite interesting if not sound scientifically. For instance, the *Ball Blue Book* advises allowing a tiny stream of steam (known as "bleeding" in factory canning) to escape during processing.* The reason given is as follows: "This is done to prevent

* "Bleeding" is a technical term applied to the act of allowing a small jet of steam to escape from the retort or cooker during processing. In this manner, air pockets and the like are avoided and the operator is more certain that all air is driven out.

FIGURE I

suction which results in drawing liquid from jar." *The Ball Blue Book* recommends a pressure of 10 lb. in the cooker with a processing time of 40 minutes for most vegetables, 60 and 90 minutes for a few others, and 120 for sweet potatoes. This would give a temperature of 240° F. These recommended processing times and temperatures are too low for such foods, processed even under steam pressure under conditions which obtain in the steam-pressure cooker. The *Kerr Home Canning Book* is still more ambiguous. It recommends steam pressure of from 10 to 15 lb. (240° F. to 251° F.) leaving the home-canner to choose which she shall use. The advice "All vegetables and meats canned at home should be boiled 10 or 15 minutes before tasting," is sound and necessary and would seem to indicate that they do not have entire confidence in their recommendations. The cooks which are recommended by both of the books just mentioned are shorter than those recommended by the U. S. Department of Agriculture. The fact that the glass container has a

marked retarding effect on the rate of rise of temperature is also important and is not given the significance due it.

Two other methods of processing have been advised since the early days of home-canning—the boiling water-bath and the oven. The boiling water-bath was advised in the earliest bulletins distributed by the U. S. Department of Agriculture. *Farmers' Bulletin 359* advised a 5 hour process in boiling water for vegetables. *Farmers' Bulletin 839* stressed the fact that any food could be canned in the home by methods recommended in that bulletin. Three methods of canning were advised—hot-water-bath at 212° F., water-seal process at 214° F., and the steam-pressure cooker. *Farmers' Bulletins 853* and *1211* retained the methods of former bulletins. *Farmers' Bulletin 1471*,⁷ appearing in 1926, showed the effects of consideration of the results of bacteriological researches. The time-tables for processing foods were arranged for acid and non-acid foods. Experience with botulism had indicated that non-acid foods (vegetables and uncured meats) must receive special treatment. *Bulletin 1471*, therefore, went the entire distance and recommended no other method than heating under steam pressure for vegetables and meats.* The controversies which led to this position were reviewed in a former paper.⁶ Even though this bulletin, revised in May, 1932, stated emphatically that hot-water-bath processing was not recommended for vegetables, the great majority of extension services and bulletins published by equipment manufacturers carried time-tables for processing in the hot-water-bath and oven. They have not accepted the

* Recommendations in this bulletin that the home-maker consult the state extension service, in case of doubt, might be questioned. This is good advice only if the extension service happens to be one which has considered all bacteriological knowledge and does not recommend boiling water processes for vegetables. This recommendation has apparently been deleted from recent revisions of this bulletin.

position assumed by the Department of Agriculture. The hot-water-bath process was apparently introduced before much was known about heat penetration. While it may be suitable for acid foods, years of experience with it have shown that it is unsuitable for non-acid foods. It does not sterilize such foods and yields a product in which there is considerable spoilage.

Oven-processing, recommended by manufacturers of some gas ranges and glass jars, is both wasteful and dangerous. Ball Brothers Company recommended this method of processing if the oven is provided with a regulator, since they claim that overheating will cause some "loss of liquid through boiling out of partly sealed jars." They advise starting the time of processing when the required temperature of 275°F . is reached with 3 hours—the maximum heating period for vegetables—even those which have caused many outbreaks of botulism. *The Kerr Home Canning Book* (1933) recommends an oven temperature of 250°F . with a

maximum heating time of 240 minutes (4 hours) for any vegetable. They claim that heating temperatures above 250°F . will cause the liquid to boil too hard and evaporate. They also recommend that processing time be counted when the oven is lighted. Such a process might result in undercooked foods. The danger of boiling is probably not serious since the "coming-up time" of the temperature of the jar is so long that 212°F . might not be reached within the recommended time, with some products at least. Furthermore, unsealed foods cannot be heated above 212°F . irrespective of the oven temperature.

Processing of non-acid foods in the oven will not result in a sterile product or in a product which will keep when stored at higher temperatures. It is probably the poorest method that can be advised for cooking canned foods. At the Indiana Agricultural Experiment Station it was found that if the initial temperature of water in a jar processed in the oven was 68°F . and the oven was

FIGURE II

preheated to 275° F., from 95 to 110 minutes were required for the contents of the jar to reach 212° F. as compared with 20 to 25 minutes in a boiling water-bath. With an initial temperature of 158° F. in the contents of the jar, the corresponding times required in the oven and water-bath were from 50 to 55 and from 15 to 18 minutes respectively. These data were secured with water. In foods solidly packed such as spinach, meat, and sweet potatoes, heat penetration would be so much slower that the temperatures at the center of the jar would not reach 100° C. in any processing time which has been suggested by those who use this method.

The success of any method of processing canned foods is determined largely by the rapidity of heat penetration into the container and the thermal destruction time of spoilage microorganisms at the pressure and temperature. This is easily understood when thermal resistance of *Cl. botulinum* at 212° and 240° F. is compared. The resistance of this organism at 212° F. is 360 minutes while at 240° it is only 10 minutes in neutral phosphate solution. Unless sufficient heat penetrates to the center of the jar to destroy microorganisms the product may spoil. Much sound information is available from careful studies long since reported by Ball,^{9, 10} Magoon and Culpepper,^{11, 12} and Bigelow, Bohart, Richardson and Ball.¹³ These publications cover the subject quite completely and present sufficient data for those advising home-canners, if they will only use them. They need not be reviewed in full, for they are available to anyone interested. Magoon and Culpepper studied the glass jar with various foods.^{13, 14}

In order to show the relative rate of penetration of heat into glass jars processed in the steam-pressure cooker,

in boiling water at 212° F., and in the oven, the curves shown in Figure II were prepared. They were secured by packing peas in regular quart jars and inserting a thermocouple through the cover to the center of the jar. The jars were then placed in the respective heating units; a preheated standard pressure-cooker, a kettle of boiling water, and a gas heated oven preheated to 250° F., for processing. The thermocouples were connected through lead wires to electrical equipment where temperatures at the center of each jar were determined and recorded at frequent intervals during the process. The heating units were operated in accordance with instructions for home-canning except that the pressure cooker was operated at 15 lb. pressure rather than at 10 or 10-15 lb., as suggested in some home-canning books. The oven was preheated in this test although some home-canning books suggest counting time from the time that the cold oven is lighted. The oven was also controlled at 250° F. instead of 275° F., as some home-canning books suggest. Figure II therefore shows the comparable rate of heating of peas in the pressure cooker and in the hot air oven, both operated at the same temperature.

The temperature in the jar located in the hot air oven should not rise perceptibly above 212° F., as the container is only loosely closed, and loss of the product will occur if heated above 212° F. The curves indicate that jars placed in an oven really heat more slowly, and do not obtain a temperature during the process above that reached in the boiling water-bath.

The pressure processes suggested for products such as peas should produce adequate sterilization, however, the boiling water processes of 180 minutes or oven processes of 180 to 240 minutes suggested by some of the prominent home-canning books will obtain only from 10 per cent to 16 per cent of the

* Not connected with a firm with a similar name.

sterilizing value of suitable pressure processes.

As the relation of inadequate processing to botulism and the relatively greater difficulty of processing non-acid foods was established, acidification of non-acid foods with lemon juice or vinegar was suggested. Having established that a hydrogen ion concentration of 4.5 had protective action by inhibiting development of *Cl. botulinum*, it was believed that this could be attained by addition of acid. Non-acid foods are highly buffered; consequently such large amounts of acid would have to be added that flavor would be affected. Sunderlin, Nelson, and Levine,¹⁴ for instance, found that acidification of asparagus and sweet corn with phosphoric or citric acid made a 2 hour process satisfactory, whereas without acid even a process time of twice as long was not sufficient.

The U. S. Department of Agriculture since 1931 has been disseminating through *Farmers' Bulletin 1471* (Stanley)⁷ satisfactory instructions to the home-canner and the department on frequent occasions has emphatically stated that non-acid foods should be processed only in the steam-pressure cooker. Despite this fact, some concerns making canning supplies to be used in the home, and many agricultural extension services still disseminate unsound, if not dangerous, advice. Dr. A. F. Woods, former Director of Research of the Department placed the department on record as follows:

There is now no excuse for continuing to take risks involved in canning non-acid foods without adequate pressure cooks.

All recommendations by this department will hereafter make this clear and emphatic.

Government and state bulletins on home-canning have not heretofore specifically disapproved water-bath processes for non-acid products. The attitude now taken by the Federal Department of Agriculture should greatly reduce the danger from understerilization of home canned foods.

The author (Tanner)⁶ has already reviewed the situation as far as publications of agricultural extension services and government bureaus are concerned. It was pointed out that only 10 of some 45 states which distribute bulletins on the art of home-canning give methods which take into account sound bacteriological knowledge. These are California, Florida, Maine, Nevada, New York, Illinois, North Dakota, Virginia, Washington, and Texas.* While a few other states have stated that non-acid foods (vegetables and meats) should be processed under pressure, they still give time-tables for hot-water-bath and oven processing. As long as such tables are published, it may be assumed that they are given at least tentative approval and are being recommended to the home-makers of the state.

Another source of information for home-canners are publications distributed by manufacturers of apparatus and supplies for the home-canner, magazine, and newspaper food bureaus. Recommendations of a number of such

* The author desires to call attention at this time to certain changes which should be made in the former paper. The letter in the table indicating that North Dakota recommends boiling water process for vegetables should be moved to indicate pressure-cooker sterilization. In the context on page 370, this state is mentioned among those with approved recommendations. Virginia should be added to the list in the context making 8 states which distribute sound advice as indicated in the table. The name McCordic (McCordic) should be deleted from the "author" column after Wisconsin. Mrs. McCordic was the author of a Special Circular, November 1932, in which the steam-pressure cooker was recommended for vegetables. Eight months later in July, 1933, *Circular 261, Home Canning and Jelly Making*, was published in which boiling water processes were recommended for vegetables. Both of these publications bear the imprint

"Extension Service of the College of Agriculture
The University of Wisconsin, Madison"
Mrs. McCordic was apparently not the author of the latest publication (*Circular 263*, October, 1933). *Extension Bulletin 183*, Extension Service, State College of Washington, June, 1933, apparently supersedes the undated mimeographed material used in the first paper. The steam-pressure cooker is now recommended for non-acid vegetables with processes given in *Farmers' Bulletin 1471*. Information is also at hand that the extension service of Maine now recommends the pressure-cooker for non-acid foods.

authorities are shown in Table II. It will be seen that a few give reliable advice about processing vegetables, recommending only the steam pressure cooker. On the other hand, much unreliable advice is still disseminated even by some of the largest manufacturers of equipment for the home-canner. Some 10 advise oven-processing which is known to be wasteful and dangerous while practically all of them recommend the boiling water-bath. Health officers would be justified in insisting that these authorities avail themselves of all bacteriological knowledge.

Many statements in these publications are both misleading and scientifically unsound. For instance the Kerr Glass Mfg. Corp., in a small booklet, *Modern Method of Home Canning*, by Kerr, states that Louis Pasteur gave us the method of pasteurizing milk and proved that growth of bacteria in foods is the cause of spoilage. It then continues, that Pasteur discovered two fundamentals of successful food preservation—complete sterilization of the product, and perfection of absolute airtight seal. The Kerr principle of sealing is said to insure achievement of these results. Complete sterilization cannot be attained by the process times and temperatures recommended on the later pages of this booklet nor in the much larger *Kerr Home Canning Book*. The type of closure on the jar has very little to do with successful sterilization. It is but one of many necessary requirements for successful canning. It may, however, prevent bacteria from gaining entrance from the outside environment after those in the food have been destroyed by the process. This same book gives as the first step for successful canning: "complete sterilization (entire destruction of all micro-organisms such as yeast, bacteria, and mold)." Such a bacteriological utopia has not yet been reached even by factory canners who are using longer cooks.

The recommendation that non-acid foods (vegetables) may be processed in the hot-water-bath and oven, can but lead to a high percentage of spoilage and occasional outbreaks of food poisoning. As long as such processing advice is given in publications, it may be assumed that those who distribute them, recommend them to the home-canner even though they may state that the U. S. Department of Agriculture recommends only the pressure cooker for non-acid vegetables and meats. There is nothing to prevent the home-maker from gaining the impression that a boiling water process is just as satisfactory for non-acid foods as a steam-pressure process. If time-tables are given for such methods of processing, it may be assumed that they are approved. The reader is left to puzzle over the many inconsistent statements.

These statements apply equally well to the *Ball Blue Book of Canning and Preserving Recipes*. It also quotes the recommendations of the U. S. Department of Agriculture to the effect that pressure cookers should be used for vegetables and meats, even though time-tables on hot-water-bath processes for these foods are given. The writer has been informed that canning instructions distributed with the "Presto" jar made by the Owens-Illinois Glass Co., and distributed by the Cupples Co., of St. Louis, are to be made to conform to good canning practice. In their present form they are not acceptable. The statements* made about the publications of several companies in the above paragraphs apply equally well to those of some other manufacturers, as shown in Table II.

* It has been difficult to determine in some publications whether the boiling water process for vegetables is approved. Statements may be made about the danger of such processing and attention called to the position now assumed by the U. S. Department of Agriculture, yet time-tables be published for boiling water. Where a publication included time-tables for such processing, the author has assumed that this method was approved.

That many of those who recommend procedures to home-canners do not have entire confidence in the products is suggested by the oft-repeated advice, "all vegetables and meats canned at home should be boiled 10 to 15 minutes before tasting," or "thoroughly re-heat all canned vegetables and meats before using." The advice is also given that if home-canned vegetables are desired for salad, re-heat and then cool before using.* The statement that the U. S. Department of Agriculture recommends the pressure cooker for non-acid foods appears frequently. These statements indicate that constant fear of food poisoning obtains in the minds of these "authorities." This fear is justified, for every year inadequately processed home-canned vegetables take their toll of human life.

The publications just mentioned are widely distributed in the United States even in those states where home economics and extension services are endeavoring to disseminate only reliable information. While state authorities are insisting on proper methods of processing, the bulletins and circulars distributed by canning supplies manufacturers may do much to interfere with this program. Despite the fact that many of these bulletins quote the position of the U. S. Department of Agriculture on pressure cooks for non-acid foods, they persist in giving the time-tables for oven and water-bath processing of these products.

Some newspaper food bureaus and magazines also disseminate unsound advice. *Capper's Farmer* for February, 1934, had an article on "Tips on Canning Meat," in which the pressure cooker and boiling water processes are

recommended—the latter to be carried out in a wash-tub. Home-makers who follow such advice are bound to have grossly under-sterilized products.

Canning contests are frequently used by some manufacturers and others to stimulate interest in home-canned foods. Foods packed for such exhibitions are judged mainly by color and appearance and not on the basis of sterility. In fact, one home canning instruction book states: "Temperatures higher than boiling tend to injure the delicate color and texture of most fruits."* The implication is then, that color and texture are paramount. Boiling water processes are generally considered to be safe for fruits if the time is sufficiently long.

A part of the unfortunate situation discussed in this paper may be laid at the doors of many departments and schools of home economics. They continue to give in courses and publications advice which is unsound. Many of their graduates are employed by commercial concerns and bureaus disseminating misinformation, and thus the situation is made more serious. Not much improvement can be expected until misinformation is stopped at its source. Those who speak with authority from any position are duty bound to give none but the safest and soundest advice. Fortunately, the situation is beginning to improve. It is significant that the radio is playing an important rôle. The author has heard two talks on home-canning in which the boiling water process was recommended for vegetables. On the other hand, he was told of another in which most trustworthy statements were made.

SUMMARY

The procedures recommended to home-makers of America by some agricultural extension services, newspaper

* This is good advice and is necessary as long as some present methods are used. It is more logical to destroy the organism itself than to attempt to destroy the toxin after it has been formed. The home-maker should make certain that the food has actually boiled for some time. Owing to numerous outbreaks of botulism at high altitudes 10 minutes' boiling may not be sufficient under these conditions

* Such characteristics should be of secondary importance to keeping quality and health hazards.

bureaus, and manufacturers of supplies for home-canners are reviewed and appraised in light of bacteriological knowledge which has been accumulated during the last 15 years. Since there have been no outbreaks of botulism caused by factory-canned foods in America since 1925, and since home-canned foods cause numerous outbreaks each year, it is suggested that this unfortunate situation may be largely due to inadequate recommendations by some of the authorities mentioned above. Arguments are developed to show that those who disseminate advice to home-canners should realize their responsibility to the public in such matters. Non-acid vegetables and meats should be processed only under steam pressure and not in the oven or boiling-water-bath. Until preservation of perishable food products by heating in wash-tubs, wash-boilers, lard cans, and other such containers is entirely eliminated, outbreaks of food poisoning will continue. Although the U. S. Department of Agriculture has placed itself on record very emphatically as opposed to the use of such methods, and distributes a reliable publication to home canners in *Farmers' Bulletin 1471*, only 10 extension services connected to state agricultural experiment stations have seen fit to adopt similar recommendations; these are California, Florida, Maine, Nevada, New York, Illinois, North Dakota, Virginia, Washington, and Texas.

Attention is also directed to the statements made in many publications of manufacturers of canning supplies for the home-maker. Many of them are not only unsound bacteriologically, but

may mislead a home-maker into situations where she may not only subject her family to serious health hazards but pack a product which will show high incidence of spoilage when stored under average conditions in the home. Health officers and other may play a rôle in directing attention to sound practice for preservation of foods by canning in the home.

Toxicity of Brilliant Green for Certain Bacteria*

EDMUND K. KLINE, DR.P.H., F.A.P.H.A.

Cattaraugus County Department of Health, Olean, N. Y.

THE purposes of this study are best described in the following resolution adopted during the Annual Meeting of A.P.H.A. in Washington in 1932.

Since the practice of incorporating dyes in culture media for the purpose of growth of certain kinds of bacteria is increasing, and since the value of such differential media is dependent upon the toxicity of these dyes; therefore, be it resolved by the Laboratory Section Council of the American Public Health Association that a committee be appointed to consider the possibility of establishing standards of toxicity for such dyes with especial reference to those used in media recognized by the Standard Methods of Water and Sewage Analysis.†

This paper reports a study of the toxic effect of various brilliant green dyes incorporated in a simple culture medium. Since primary interest concerns the ability of the dye to inhibit growth in various media the emphasis

has been placed on bacteriostatic rather than bacteriocidal action.

Bacteriostasis is probably simply a manifestation of vital staining, wherein the reproductive mechanism of the organism is destroyed or at least rendered inoperative. All of the theoretical considerations and experimental evidence that have been advanced regarding the mechanism of staining reactions is applicable in some degree to the present problem. Excellent reviews of literature dealing with this are available.^{1, 2}

DETERMINATION OF BACTERIOSTATIC TITER

There are several possible ways of determining experimentally the bacteriostatic powers of various lots of dyes.

1. Measuring the smallest inoculum that will initiate growth—A method previously used by Dunham and open to the drawback that there is no satisfactory way of measuring small inocula except by dilution methods and that these are subject to rather wide chance variations as the number of organisms in the inoculum becomes very small.

2. Measuring the rate of multiplication following a standard inoculum—The method used by Dunham and Schoenlein in their work on bile brilliant green media in 1926 for the Standard Methods Committee of the American Water Works Association.³

3. Measuring the lag phase in the presence of dye in relation to the normal lag phase in control media—A method for the quantitative determination of bacteriostatic action recently devised by Mary A. Ingraham, University of Wisconsin.⁴

* While this was read as a paper, it is also to be considered as a report from the Referee, presented at the request of the Standard Methods Committee, to the Laboratory Section of the American Public Health Association at the Sixty-third Annual Meeting in Pasadena, Calif., September 4, 1934.

† With the reorganization of the Standard Methods Committee this problem was assigned to the section on Diagnostic Methods and Procedures and the author was appointed Referee for this study. Dr. H. J. Conn, Chairman of the Biological Stain Commission and H. G. Dunham, of the Difco Laboratories, both of whom are pioneers in the field of dye standardization, have served as Associate Referees. Advice and assistance have also been received from Harry Jordan of Indianapolis, Dr. Max Levine of Iowa State College, and Frank E. Hale of the Mount Prospect Laboratories of New York City Bureau of Water Supply. The work has all been performed by the Referee in the laboratories of the Cattaraugus County Department of Health, Olean, N. Y.

+ Signs indicate bacteriostasis (no growth of bacteria). - Signs indicate growth. Double columns indicate duplicate tubes.

All of these tests in lactose-peptone broth pH 6.9.

4. Measuring the concentration of dye that will inhibit gas formation—The method used by Hale in previous work for the Biological Stain Commission.

5. Measuring the concentration of the dye which will inhibit growth with a standard inoculum.

the results included—composition and reaction of the media, concentration of the dye, activity of the organisms, composition of the diluent, and size of the inoculum.

OUTLINE OF METHOD

Medium—A base medium consisting of 1 per cent Bacto-peptone and 1 per cent Bacto-lactose was chosen. Unadjusted, it had a reaction of pH 6.9 after sterilization.

In devising a procedure to be used in the present studies it seemed that the last method was the simplest and most likely to be properly controlled. The variable factors which might influence

The final volume in the test might conveniently be 10 c.c. A number of test tubes were marked at $7\frac{1}{2}$ and at 10 c.c. Ten grams of Bacto-peptone and 10 gm. of Bacto-lactose were dissolved in 750 c.c. of distilled water, tubed in $7\frac{1}{2}$ c.c. amounts and sterilized in the autoclave. After the addition of the dye and the inoculum, sterile water was added to each tube to bring it to a volume of 10 c.c. so that the medium during the time of incubation had the concentration of the simple base medium.

Dye—The dye was used as an aqueous solution in distilled water prepared in volumetric flasks and added to the medium in such dilution that not more than 2 c.c. nor less than 0.2 c.c. was added to each tube.

Inoculum—After the organisms had been established in the simple base medium (1 per cent Bacto-peptone and 1 per cent Bacto-lactose) by a series of daily transfers, a transfer was made and examined at half-hour intervals until a distinct turbidity was noted. A loopful of this culture was then placed on a hemocytometer under a thin cover slip and examined and counted under oil immersion. If the average number of bacteria present was between 1 and 5 per small square (between 4 million and 20 million per c.c.), the culture was diluted with sterile water to which had been added 1 per cent of the base medium so that the final concentration was approximately 200 per c.c. One-half c.c., or approximately 100 organisms, was then used as the inoculum for each tube.

Test—Proper quantities of the dye to give the concentrations desired in 10 c.c. were added to the tubes by means of sterile pipettes. Each tube was then thoroughly shaken. Dilutions of the culture were prepared in the manner described above, and $\frac{1}{2}$ c.c. of the final dilution, approximately 100 bacteria, was added to each tube. The volume of

each tube was then made up to 10 c.c. by the addition of sterile water by means of a sterile pipette. The tubes were again shaken (in a mechanical shaker) placed in the incubator, and examined for growth at the end of 24 hours and each day thereafter for 5 days. It is recommended that each test be set up in duplicate. Results are recorded as growth or no growth.

NOTES—The simple peptone broth chosen as the base medium supported excellent growth of all the organisms used.

The above method of estimating organisms is one commonly used for counting vaccines. Slight deviations in the size of the inoculum, 50 to 150 organisms rather than 100, did not materially alter the bacteriostatic titer.

The object of using the young culture was to place the organisms in the dye medium at a time when they were in the logarithmic growth phase at which stage they should be most active. The organisms were diluted in a weak culture medium to protect them against the bactericidal effect of distilled water.

The bacteriostatic action of the dye affects the growth of bacteria during the lag phase. It has been found that after this phase immediate and very heavy growth is apparent so that there is no difficulty in determining which tubes show growth by simple examination.

Materials — The Dye Commission furnished samples of several lots of brilliant green including all of those now on the market and Dunham a sample of the original dye (# 190) that he used in the studies of bile brilliant green media on which the present standard medium is based.

Five different organisms were used, *Escherichia coli*, *Aerobacter aerogenes*, *Citrobacter sp.*, *Bacillus subtilis* (Marburg type) and *Bacillus cereus*.

Range of Bacteriostasis—Using the above method high dilutions of the dyes proved to be bacteriostatic. Members of the colon group were usually inhibited between 1:200,000 and 1:400,000, while the spore forming organisms were usually inhibited from 1:10,000,000 to 1:50,000,000. However, test

sets could not always be duplicated in regard to the concentration of dyes which would inhibit or permit growth. For instance, using *Aerobacter aerogenes* and NBg 5, growth was obtained in some series in as low a dilution as 1:25,000 and in other series no growth appeared in dilutions as high as 1:125,000.

Variations within a Test Set—Duplicate tubes within the set usually checked each other very closely but, as would be expected in a biological test of this nature, in a few instances a variation of two or more dilutions occurred.

Aftergrowth effects were frequently encountered wherein tubes negative in 24 or 48 hours would show vigorous growth at later periods. This undoubtedly represented lag phases delayed for periods of 24 hours to a week. It was not surprising to find this as it has frequently been possible to train bacteria

to become dye resistant. Working with brilliant green and *Escherichia coli*, Mary V. Reed and Elizabeth Genung have recently reported a multiplication of 250 times in tolerance of the organism for the dye through 13 transfers to stronger and stronger dye media in 56 days.⁵

Comparative Test Sets—When two dyes, CBg 4 and NBg 5, were set up in parallel series CBg 4, exhibited a markedly stronger bacteriostatic effect, whatever organism was used, as can be seen from Table I.

The 8 available dyes were set up against *Aerobacter aerogenes*. Growth extending over a week of incubation appeared very similar to that already shown. The results at the end of 24 and 48 hours incubation are shown in Table II a.

This experiment was repeated using *Bacillus cereus* with results shown in Table II b.

+ Signs indicate bacteriostasis (no growth of bacteria). - Signs indicate growth. Double columns indicate duplicate tubes.

All tests in lactose-peptone broth at the pH indicated.

CHART I

In view of the fact that brilliant green is commonly used in water analysis in combination with bile at a pH more alkaline than 7.0 it was thought desirable to determine whether the dyes would act the same at a higher pH. Therefore, the above experiment was repeated with a medium of pH 7.25 and essentially the same results obtained, as shown in Table II c.

In order to compare the results given in the last 3 tables the average readings of the tubes shown in those tables are plotted as a curve in Chart I.

DISCUSSION

A method has been presented by which it seems possible to determine the bacteriostatic titer of any given sample of brilliant green. Using this method indications have been obtained that there are distinct differences in the relative toxicity of various batches of this dye. One particular batch, for instance, has been found distinctly more toxic and another distinctly less so than the average run of samples. Data are still too meager, however, to permit definite conclusions at the present time.

It is hoped that other laboratories may be stimulated to check this work and that if possible other methods of measuring bacteriostatic titer can be utilized as a further check. The im-

portance of laboratories doing experimental work recording, in every instance, the lot number of the certified dye which they are using should be again emphasized at this time. The Referees are most anxious to obtain reports of any work which has a bearing on this subject. They in turn will be glad to furnish information on any of the dyes tested to persons interested in bacteriostatic titers.

The dyes which have been used in these experiments include samples of all lots of brilliant green now on the market under certified labels.

The Biological Stain Commission will hereafter refer all samples of brilliant green submitted to them to the Referee, and bacteriostatic titers will be determined and these will be available to any laboratory interested in them.

The Plague Situation^{*}

W. H. KELLOGG, M.D., F.A.P.H.A

Chief, Bureau of Laboratories, State Department of Public Health, Berkeley, Calif.

IT is just 40 years since the present pandemic of plague began with the appearance of an epidemic in Hong Kong and just 34 years since it reached California. Arriving in India from Hong Kong it found favorable conditions and soon after 1900 the deaths reached a million per year. Even now after nearly 40 years of continuous activity the deaths from plague in India are occurring at the rate of 3,000 to 4,000 per week. Considered in the light of the known history of plague there is nothing unusual in these facts, nor is there in the length of time it has been continuously present in California any ground for believing that it is dying out and will shortly disappear.

It is characteristic of plague that its period is very slow and the rise and fall of epidemics is measured in decades and centuries. Upon its appearance in a country it is sometimes years before its presence is manifested by any great mortality, and in the subsidence of a pandemic its final disappearance is interrupted by sporadic localized outbreaks. The long range periodicity of plague, as well as its persistence, is well shown in the history of plague in England where it finally disappeared in 1680 after an almost continuous presence for 136 years. The Great Plague of London occurred in 1665 with about 70,000 deaths, but there had been previous to that time and within the 136 year period 5 epidemics with from

10,000 to 35,000 deaths at intervals of 30, 10, 22, 11 and 30 years.

The following from Procopius of Caesarea, in his History of the Persian Wars describing the pandemic of the 6th century—which is the first authentic historical pandemic—is interesting in its parallelism with more modern appearances:

It arose in Egypt with the inhabitants of Pelusium, then dividing spread one way through Alexandria and the rest of Egypt, the other into Palestine which borders on Egypt, and then traveled over the world always advancing with a progress marked by certain definite spaces of time. For it seemed to advance by a certain law and to demand a certain space of time in every country, discharging its venom against no one on the way casually, but spreading on this side and on that to the uttermost ends of the world as if it feared lest incautiously it should pass by any corner or recess upon earth. It spared neither island nor cave nor mountain top where man dwelt. If it passed over any place only slightly or mildly touching the inhabitants, it returned there afterwards leaving untouched the neighbors against whom it had spent its rage before and it did not depart from there before it made up the full measure of the dead in proportion to the amount of destruction which it had brought on its neighbors. Always beginning at the sea coast it spread into the interior. In the second year it reached Byzantium about the middle of the spring where, as it happened, I was staying.

The great epidemics of ancient times seem to have been of the bubonic form, although it must be remembered that historical accounts of plagues include all epidemic disease, typhus, smallpox, etc., as well as plague, and it is only the description of buboes by some of the writers that identify bubonic plague. Pneumonic plague might have occurred,

^{*} Read before the Health Officers Section of the American Public Health Association at the Sixty-third Annual Meeting in Pasadena, Calif., September 4, 1934.

but for authentic accounts of pneumonic plague epidemics we have only comparatively small outbreaks in recent years in Manchuria, in limited districts of India, and on a still smaller scale in California. There are, however, references seeming to indicate that pneumonic plague accompanied some of the bubonic outbreaks and therefore doubtless occurred alone.

Guy de Chauliac in his description of the plague at Avignon, which was part of the second historical pandemic in the 14th century, says:

The plague commenced with us in January, it continued seven months during which time it appeared in two forms. During the first two months it was accompanied with a continuous fever and with a coughing of blood. All who were attacked died in three days. During the other months the continuous fever was accompanied with tumors and boils which appeared in the external parts of the body, chiefly in the arm pits and in the groin. Those who were thus attacked died in five days.

As with illness of the individual, the prognosis is of great interest and importance to him, so also with the commonwealth, when plague is endemic is a prognosis of interest. Reviewing the past history of the disease an attempt may be made to predict what the future has in store for California and for the rest of the nation. It soon develops, however, that about the only thing that is certain about plague is the uncertainty of its disappearance and that usually about a century is required for it finally to flicker out. This is the history of human epidemics. But how about the endemic foci where plague lies dormant during the intervals between epidemic or pandemic spread? The natural reservoir of plague is in wild rodents of squirrel or groundhog type and the historical foci are districts in Arabia along the Red Sea, in Mesopotamia, in Thibet, in Yunnan in China, and in Uganda in Africa. More recently endemic foci have been estab-

lished in Manchuria from which the pneumonic epidemics of 1910 and 1916 originated, and in California where the native rodent concerned is the ground squirrel, *Citellus Beechii*.

The rat as a carrier of plague seems to be subject to the rise and fall of epidemics the same as is his human associate. When plague disappears from a human population it leaves the rat population also, but the enzoötic does not exactly coincide with the epidemic. It usually precedes it and is likely to linger longer. The source of human bubonic outbreaks is the rat and the source of rat plague is doubtless contact with wild rodents in some endemic focus. The primary source of plague, therefore, is the wild native rodent and the distributor is the rat which travels in ships and visits all lands. The rat occasionally returns the infection to wild rodents in some new locality, thus establishing a new endemic focus. This happened in California shortly after the introduction of plague into San Francisco about 1900,¹ and presumably the point of contact was in the vicinity of the Port Costa warehouses. At any rate squirrel plague was first found in that vicinity, and the enzoötic soon reached large proportions.

The record of plague in California is as follows:

March, 1900—Bubonic plague appeared in San Francisco, principally in the Chinese colony, and a total of 121 cases with 113 deaths occurred over a period of 4 years.

May, 1907—Bubonic plague again appeared in San Francisco. The total number of cases over a period of 6 months was 160 and the deaths 78. This time it was not confined to Chinatown, but scattered over the whole city.

August, 1908—Plague proven to be present among the ground squirrels of Contra Costa County.

May, 1907, to December, 1918—Sporadic cases of human plague to the

number of 11 with 5 deaths occurred in the counties of Alameda, Contra Costa, San Benito, Santa Clara, San Joaquin, and Stanislaus. Squirrel plague found to be present in the same counties as well as in Fresno, Monterey, San Luis Obispo, Santa Cruz, San Mateo, Merced, and San Francisco.

August, 1919—An outbreak of pneumonic plague in Oakland with 13 cases and 12 deaths.

1919 to 1924, inclusive—Six sporadic cases with 2 deaths occurred in Alameda, Monterey, San Benito, and Santa Cruz Counties.

October, 1924—An outbreak of pneumonic plague in Los Angeles with 32 cases and 30 deaths.

November, 1924—Five cases of bubonic plague with 3 deaths in Los Angeles County.

1925 to 1933—Seven sporadic cases with 5 deaths in the counties of Los Angeles, Santa Cruz, Monterey, and Santa Barbara.

1934—One human case in Tulare County. Also a large epizootic among ground squirrels of Tulare and Kern Counties, over 200 positive specimens being found among those sent to the laboratory. Furthermore, an epizootic was discovered among the ground squirrels of Modoc County in the northeastern corner of the state on the eastern side of the Sierras.

This chronology of plague in California shows that we have had 2 bubonic epidemics, the first in San Francisco from 1900 to 1904, and the second in San Francisco and Oakland in 1907 and 1908. We have had 2 pneumonic epidemics, the first in Oakland in 1919, and the second in Los Angeles in 1924. We have had in all 35 sporadic cases with 19 deaths, mostly in rural districts and of squirrel origin, 9 counties being represented. Squirrel plague has been found in 19 counties.

The plague situation on the West Coast is of interest to health authorities

throughout the country as will be appreciated by a consideration of what the possible answer is to certain questions which immediately present themselves: First, what is the probability of plague dying out before long? Second, what is the significance of ground squirrel infection? Third, is plague in California a menace to other states?

The answer to the first question is written in the history of plague, and from the brief references to that history already quoted in this paper it may be suspected that the chapter is not finished and may not be for many years to come. This is made all the more certain when it is remembered that there is every reason for believing that the historical epidemics and endemics were rat-borne and in course of time they did come to an end, whereas plague has been kept alive continuously in particular habitats where the rodent concerned was not the rat but a wild native animal such as the marmot. In these localities plague has not, so far as anyone knows, ever completely disappeared. Such a focus now exists in the California ground squirrel.

In answer to the second question we find the most disquieting aspect of the whole problem. In rat plague pneumonia is not a common finding. Guinea pigs inoculated from rats rarely show lung involvement. In squirrel plague pneumonia is common. Guinea pigs inoculated from squirrels very frequently present a pneumonia. The Oakland outbreak of 13 pneumonic cases, which group included 2 nurses and 2 doctors, was started by contact with squirrels, the first man having been squirrel hunting just before his onset. His case was primarily bubonic (axillary) with pneumonia supervening. The Los Angeles epidemic is not so easily traced to squirrels although in the rodent survey following, both rats and squirrels were found infected. There would seem, therefore, to be some

ground for the theory that pneumonic plague is the result of a development of a specific organ virulence on the part of the prevailing strain of *B. Pestis* by passage through a particular species of rodent. In this connection Dr. Wu Lien Teh says ²:

The idea that the species of rodents involved in the epizootics might influence the character of subsequent epidemics is a very fascinating one. Especially it has to be considered if a close relation does exist between epizootics in certain wild rodents and human outbreaks of pneumonic plague. In fact, a world-wide study of the disease both in rodents and in man as undertaken by our staff within recent years has yielded many data supporting this view. On the other hand, in some countries where only ordinary rats are involved the incidence of lung pest is conspicuous also. But before reaching any final conclusions the following points should be considered: (1) Though ordinary rats are sometimes found to be the original source of pneumonic outbreaks, in many instances the local rodents were not involved, the disease having been imported from outside by human agency, namely, by travelers incubating the disease. (2) How long has the disease existed in the local rats? In some plague areas with rat epizootics pneumonic plague was frequent soon after the introduction of infection but became rarer afterwards. One might consequently suggest that the longer the infection continues among ordinary rats the less chance there is for pneumonic plague to appear in man.

Finally, the significance of ground squirrel infection, leaving out of consideration any bearing it may have on the type of human plague, lies in the fact that a new endemic focus has been established and these endemic foci, constituted as they are of wild rodent infection, are so far as anyone knows at present permanent and everlasting.

The third query—Is plague in California a menace to other states?—I would answer by saying, yes, for the following reasons: (a) Because of the possibility of direct extension of the disease in the wild rodent population across state lines. We have recently discovered plague among the ground

squirrels of Modoc County, 400 miles from the nearest previously known plague area and close to the state lines of both Oregon and Nevada. For all we know it has already crossed over into both states. (b) It may travel by transference to the rats in some borderline urban area, the rats traveling, as is their wont, in freight cars or ships to new and distant localities. (c) The last reason to be mentioned necessitates a return to the epidemiology of pneumonic plague. Teague and Barber,³ as a result of their investigations in Manchuria, believe that the essential conditions for a rapid spread of pneumonic plague are a low temperature with considerable humidity, thus permitting droplets containing plague bacilli to remain suspended in the air a longer time and at the same time preserving them against the destructive influence of warmth and drying. They point out that the greatest pneumonic epidemic of modern times occurred in Manchuria in the winter of 1910–1911 when the temperature was many degrees Centigrade below zero; also that in India only 2 to 5 per cent of the cases are pneumonic and no large pneumonic outbreaks have occurred there except one with 1,400 deaths in Kashmir at an elevation of about 5,000 feet and in very cold weather. If we accept the plausibility of Teague and Barber's thesis we must admit the possibility of some person during the incubation period of plague traveling east in the winter time. Should this traveler develop an axillary or cervical bubo with a secondary pneumonia, the stage will be set for a rapid man to man transfer of a form of the disease that has no rival in the rapidity of its spread and the certainty of a fatal outcome.

Rôle of the Sanitary Inspector in the Public Health Program*

C. E. WALLER, M.D., F.A.P.H.A.

Assistant Surgeon General, U. S. Public Health Service, Washington, D. C.

PHYSICISTS tell us that if it were possible for us to rise straight up from the earth at a rate of speed greater than the speed of light, theoretically we should be able, if we could stop our flight and remain stationary, to look downward and see unfolding before us the history of the past. If we could ascend high enough, we should be able to witness important events which took place centuries ago. It would be most interesting if we could, in this manner, look down today upon the health activities of the average small city of 30 or 40 years ago in this country, and follow, up to the present time, the rapid evolution of scientific public health practice which has taken place within the past 3 or 4 decades.

We should see, before the beginning of this rapid evolution, little or nothing of the well developed, efficient, scientific health organization such as we have in most of our large cities and many of the smaller ones today. Looking into the organization and activities of the average small urban community of 40 years ago we probably should see no health department at all. The health officer, if there were one, would be a physician engaged in private practice, employed on a part-time or fee basis chiefly to administer medical care to the indigent and

to prisoners in the city jail; or perhaps he would not be even a part-time physician. He might be a lay individual, without training, whose duties would be concerned chiefly with the enforcement of such health laws or regulations as existed at that time. The part-time medical health officer would do some vaccinating when smallpox appeared in the community; he would order cases of smallpox to the pest house; he would direct the sanitary inspector, if there were one, to put up the yellow flags on houses where cases of the more dangerous communicable diseases might exist; he would order the fumigation which must follow every case of contagious disease; and occasionally would direct that all damp places about private premises be thoroughly limed. The sanitary inspector in the smaller cities frequently would be some member of the police force occasionally utilized on quarantine work or inspection of premises.

I can well remember how, as a boy, I used to spend hours cleaning and liming the place where our kitchen sink drained, especially when typhoid fever would appear in the community and we were directed by the city sanitary inspector to "clean up." Most of the people and a considerable number of the health officers of that day still believed that communicable diseases were caused by sewer gas, stagnant ponds and the like. It was quite generally accepted that diseases like typhoid fever

* Read at a Joint Session of the California Association of Sanitarians and the Public Health Engineering Section of the American Public Health Association at the Sixty-third Annual Meeting in Pasadena, Calif., September 4, 1934.

could "breed" *de novo* in filth or dampness.

I recall quite vividly the days of the "shot gun" border quarantine maintained by the states when yellow fever would prevail in the South, and I remember seeing mail perforated to facilitate fumigation when it was thought that yellow fever might be transmitted through the medium of a letter. I have heard older officers of the Public Health Service tell of the days when the rock ballast of ships was disinfected with bichloride of mercury, and even a locomotive was swabbed in a disinfecting solution, to prevent the spread of yellow fever. In the meantime, the *stegomyia* mosquito—since, in keeping with progress, given the more up-to-date name of *Aedes aegypti*—went merrily along with its business of spreading the deadly "yellow jack." It had not generally become known that malaria is a mosquito-borne disease, and people still feared the "night air" from swamps. The green scum on a pond was considered deadly. Milk was given little consideration as a possible vehicle of infection. When an epidemic of typhoid fever occurred in a small town it seldom excited suspicion that the municipal water supply might be polluted. Sewage was piped to the nearest creek or river and a sewage disposal plant was a refinement rarely seen. No one thought of the insanitary privy as playing an important part in the spread of intestinal infections in small towns and rural communities. Most of the "outhouses," as they were called, were of the open-back type; the excreta were deposited on the ground and the accumulations were removed only when it became absolutely necessary.

At that time, although considerable progress had been made in the identification of the organisms causing many of the communicable diseases, comparatively little was actually known of the epidemiological factors responsible for

their spread. Communicable disease control consisted, in large measure, in effort to prevent the spread of infection by application of police measures to prevent contact—isolation and quarantine—and in terminal disinfection, chiefly fumigation.

Then came the challenge of efficiency of police methods from Dr. Charles V. Chapin, recently retired as Health Officer of Providence, R. I., after 40 years of distinguished service, who presented an entirely new conception of scientific control of communicable diseases and demonstrated the soundness of his views by putting them into practice in his own community. Rapid progress began to be made in working out and establishing the epidemiology of many of the communicable diseases. Gorgas, Carter, and LePrince showed the way in the control of mosquito-borne diseases in Cuba and in the Canal Zone. Lumsden, of the Public Health Service, demonstrated in Yakima County, Wash., that the prevalence of typhoid fever could be reduced in large measure in rural and semi-rural communities by installing sanitary privies.

Stiles discovered the widespread existence of hookworm disease in the southern states, and the Rockefeller Foundation brought forward the sanitary privy as a means of protecting the population from this scourge. It is interesting to note that the full-time county health unit of today had its beginning largely out of the early work done by the Public Health Service and the Rockefeller Foundation and the state health authorities coöperating with them to improve excreta disposal conditions in the rural areas. At about the same time the importance of other purely environmental factors in the spread of communicable diseases began to be more widely recognized. The need for certain technical knowledge and training not possessed by the medical health officer became apparent, and

the result was the development of the public health engineer. The duties of the sanitary inspector underwent a revolutionary change and he began to find an important place in a scientific program for the real control of communicable diseases.

The sanitarian of today who would intelligently plan measures for the control of communicable diseases must constantly bear in mind the fundamental truth that the perpetuation of every communicable disease is dependent upon 3 factors: (1) the existence of a source of infection—the sick individual, the “carrier,” or the infected animal; (2) the availability of susceptible individuals or animals; (3) the existence of a means of transmission of the infection from the sick to the well. These factors may be likened to the links of a chain in which the infected individual or animal and the susceptible host take the part of rings, joined together by the events of communication. New links are constantly being added as the infection is communicated from one individual to another; and the forging of the chain continues indefinitely unless the progress of the disease can be interrupted by removing one or more of the links. The point at which the chain may be broken most easily varies with the particular disease with which we may be dealing. In some instances the only practicable method of attack available lies in an attempt to remove the source of infection—by isolating the infected individual or rendering him non-infective through treatment; in others, the elimination of the susceptible human host through immunization, or the eradication of animal hosts, such as rodents responsible for the spread of bubonic plague and typhus fever, may present the most effective means of breaking the chain; while in still another group of diseases the greatest promise of success lies in efforts to interrupt communication of the infection

from the sick to the well by removing the channels through which the infection may be carried. Some of the communicable diseases present opportunities for attack at 2, or perhaps all 3, points in the chain; and here one may elect to direct his control activities at 2 or 3 points, or he may choose to concentrate his attack on what he believes to be the most vulnerable single link.

The determination of what may be the most effective method of attack must be based upon thorough knowledge of the epidemiology of the disease. Since certain diseases, or groups of diseases, can be transmitted only through more or less definitely established channels, or may present only limited opportunities for breaking the chain of infection, efforts toward control must be specific if they are to be effective.

The public health administrator must know where the attack can be directed to best advantage in the control of each disease, and, if his facilities are limited, he must be prepared to choose wisely in selecting methods and determining the point or points upon which he will concentrate his activities.

I am reminded of the story about the highly specialized mechanic who was called in, after a number of others had failed, to determine what was wrong with a certain complicated engine which could not be started. After examining the engine very carefully for a few minutes, this mechanic selected a particular part of the engine and struck one blow with his hammer, whereupon the machine started immediately. He then rendered a bill for \$500 for his services. The owner of the engine objected to what he thought was an overcharge and demanded an itemized statement. The statement received read, “Five dollars for one tap, and \$495 for knowing *where* to tap!”

We know now that the control of communicable diseases must be based upon thorough knowledge of the epi-

demological characteristics of each disease and that our control activities must be specific to be effective. We have learned that some diseases will yield most readily to environmental sanitation—the safeguarding of water and milk supplies, improvement of excreta disposal conditions, eradication of animal hosts, and the like; that others may be controlled effectively only through protection of the susceptible human host; and that in still others the only hope of success at present lies in control of the sick individual by isolation or treatment, or in reducing mortality through the prevention or management of the serious complications of certain acute infections. We have gained a new conception of what the control program of the modern health department should be and have seen that the program of today must bring into play the combined resources and activities of the health officer, the sanitary engineer, the sanitary inspector, the public health nurse, and the practising physician.

The sanitary inspector of this day is, or should be, least of all, just an inspector and a law enforcement officer. If he is experienced and wise, he knows that an attempt to perform public health work through law enforcement alone does not produce the best results. After all, accomplishment in much of our public health procedure lies in what we may be able to persuade the individual to do for himself. The trick behind success in public health work, as well as in all other movements for the public welfare where coöperation of the individual is essential, is leading people to do things because they *wish* to do them.

There is a very definite place for the sanitary inspector of today in the modern program for the control of communicable diseases. Just as the public health nurse is taking the place of the old-time quarantine officer in the application of control measures carried out

in the home and school and making for herself a well defined and essential position in the health department, so the sanitary inspector, if he be assigned to proper duties, can become one of the most important and essential components of the organization for control of communicable diseases in his community. To make his work effective, however, his part in the program must be just as carefully planned and defined as any other activity of the health department. The "hit and miss" activities of other days were wasteful and ineffective.

The sanitary inspector should have definite objectives toward which he may work. I like to look upon the sanitary inspector as the executive for the health officer and the public health engineer; in the local health department he may be likened to the construction engineer, who takes the architect's design and specifications and builds a bridge or a modern "sky-scraper." The health officer and public health engineer study the health problems of the community; they determine which of these problems are most important and what measures must be applied to solve them and single out certain epidemiological factors to be controlled; and to the sanitary inspector is assigned the duty of applying the measures required in reaching the objective. Thus we see the sanitary inspector, in his proper rôle, not merely inspecting dairies, but undertaking to produce a safe milk for his community; not merely inspecting premises, but making it his business to see that there is a safe, sanitary means of excreta disposal and a safe water supply for every home in his jurisdiction. In the southern states we also see him carrying out a well planned program for the eradication of the malaria carrying mosquito.

Too often we have seen the sanitary inspector serving as the chauffeur for the health officer because the latter liked

to have company, or for the nurse because she could not drive a car. Or perhaps it has been convenient to have the inspector around the office to perform odd jobs and do the errands. In many health departments it is still the practice to use the sanitary inspector chiefly as a "trouble-shooter"—to answer complaints and investigate nuisances—and the health officer has no plan of work for him. Since the health department is a service organization, often dependent for its continued existence to a considerable degree upon the good will and moral support of the people, these minor complaints cannot be ignored, even though the nuisances may have little or nothing to do with the health of the community. Every health department should capitalize opportunities to render service to individuals and be pleasant about it. At the same time, the waste of effort on the investigation of nuisances should be reduced as far as possible by patiently

educating the public and creating the demand for service that gives real health protection to the community.

In my opinion, a sanitation program can be carried out successfully only when it is made a part of the activity of a complete local health organization, operating under the direction of a full-time trained health officer. The proper approach to the control of disease in every community is a study of the problems of that particular community. When the special problems have been determined and the plans have been laid, the activities of the sanitary inspector then can be directed where they will be most effective. The work of the sanitary inspector can become one of the most important parts of an essential welfare service, and such an officer may have the satisfaction of rendering a very real and necessary service to humanity if his activities are directed in the proper channels and he knows where and when to "tap."

Nutritive Value of Dried Fruits^{*}

AGNES FAY MORGAN, Ph.D.

Laboratory of Household Science, University of California, Berkeley, Calif.

THE palatability, keeping quality, and low cost of dried fruits result in their extended consumption, particularly in winter, and in parts of the world not well supplied with fresh fruits; consequently the nutritive value of these foods assumes some significance to those concerned with public health. Changes in such value brought about by the methods used in drying must be known and improvements suggested to prevent loss.

Such a research project was begun in 1927 at the University of California with the assistance of funds provided by the Purnell Act, and was continued until 1933 when it was discontinued for lack of funds. During these 6 years the main effort was directed toward the determination of the effect of various methods of drying upon the vitamin content of the fruit.

The method used was quite uniform, the Division of Fruit Products of the College of Agriculture being responsible for the procuring, experimental drying, and chemical analysis of the samples, and the Department of Household Science for the actual biological testing. In all cases fresh fruit from the same orchards was preserved by freezing storage as representative of the original condition of the fruit. Peaches and prunes of the crop of 1927, and apricots and prunes of 1928, were tested

for vitamins A and C, apricots again in 1929 and in 1930, Calimyrna and Kadota figs in 1929 and black Mission figs in 1930. Thompson seedless grapes and raisins were prepared and tested in 1931 for vitamins A, C, B, and G, as were Kadota and Adriatic figs of 1932. In addition some work has been carried on during the last year upon B and G content of peaches and apricots and a thorough study of the B and G content of commercially dried California prunes has been made. The vitamin content of Asiatic and California grown dates of known history, crop of 1930, has also been determined.

Altogether, peaches of 2 crops, apricots of 4, prunes of 4, 4 kinds of figs of 3 crops, raisins and dates each of 1 crop have been secured, dried and stored under known conditions and tested by standard biological methods for vitamins A and C, and in some cases also for B and G.

The chief questions were:

1. What proportion of each of these 4 vitamins present in the fresh fruit is retained in the sun-dried or dehydrated products?
2. What advantage, if any, has artificial dehydration over natural sun-drying?
3. What effect has the use of sulphur dioxide during the drying process upon each of the vitamins?
4. What happens to the retained vitamins during the cooking and processing of some of these dried fruits?
5. Does sun-drying develop any antirachitic activity in these fruits?

^{*} Read before the Food and Nutrition Section of the American Public Health Association at the Sixty-third Annual Meeting in Pasadena, Calif., September 3, 1934.

TABLE I
SUMMARY OF VITAMIN A RETENTION IN DRIED FRUITS

Fruit	Amount containing 1 International unit of Vitamin A			Vitamin A retained
	Fresh	Dried	Equiv. in fresh wt.	
	mg.		mg.	per cent of amt. in fresh
Peaches (Muir)	100-160	Unsulphured, dehydrated	178	90
		Unsulphured, sun-dried	177	90
		Sulphured, dehydrated	140	100
		Sulphured, sun-dried	186	86
Prunes	100 or less	Sulphured, dehydrated	109	91
		Sulphured, sun-dried	163	61
		Unsulphured, sun-dried (commercial type)	222	45
		Unsulphured, sun-dried	232	43
		Unsulphured, dehydrated	240-420	41-24
Apricots	25 or less	Sulphured, dehydrated	49-123	20-51
		Sulphured, sun-dried	118-144	16-21
		Unsulphured, dehydrated	146	16
Thompson seedless grapes	2,000		gm.	
		Dehydrated, sulphured and unsulphured	2.0	100
		Sun-dried, sulphured	10.2	20
		Sun-dried, unsulphured	13.6	15

6. What effect has the preparatory lye dipping of prunes, raisins and other fruits upon their vitamin value?

Definite answers have been found to most of these questions as regards vitamins A and C and in large measure also for vitamin B (B_1), but not so definitely as yet for G (B_2). The technic of testing for the group of B vitamins is apparently not so satisfactory as those for A and C, although the use of pigeons in testing for the antineuritic vitamin (B_1) assists materially in that case.

It is now quite obvious that the vitamins have distinct and discoverable chemical structures, each of which has apparently no relation to that of any of the others. It cannot be anticipated therefore that any procedure or reagent should have either an equally adverse or protective effect upon all of

the vitamins; nor is it necessarily true that the same vitamin will be affected to the same degree in different fruits, since the concomitant substances which may enter into the reaction may well vary in kind and amount in the various fresh fruits.

Our findings may be summarized as follows:

1. As shown in Table I, the retention of vitamin A was 86 to 100 per cent, in all dried peaches whether sun-dried or dehydrated, sulphured or unsulphured; ranged from 60 to 90 per cent in the sulphured and from 25 to 50 per cent in the unsulphured prunes; and was lower, about 25 per cent, in the apricots.^{1, 2, 3} The vitamin A of apricots is most variable in its response to various conditions but it is extraordinarily rich in the fresh fruit and even after considerable loss is found in

TABLE II
SUMMARY OF VITAMIN C RETENTION IN DRIED FRUITS

Fruit	Method of preparation	Minimum daily dose required to protect against scurvy	Vitamin C retained during drying
		gm. (equivalent in fresh fruit)	per cent
Peaches	Fresh (frozen)	5-8	100
	Unsulphured, dehydrated, and sun-dried	up to 40 gm. tried	0
	Sulphured, dehydrated, and sun-dried	6-12	100
Prunes	Fresh (frozen)	10-20	100
	Lye-dipped, sulphured, dehydrated & sun-dried	11-17	100
	Not lye-dipped, sulphured, dehydrated & sun-dried	17-32	0 to 50
	All unsulphured products	up to 40 gm. tried	0
Apricots	Fresh (frozen) 1928 crop	up to 30 gm. tried	0
	Fresh (frozen) after evacuation, 1929 crop	10-15	100
	All products with less than 500 p.p.m. SO ₂	up to 72 gm. tried	0
	All products with more than 500 p.p.m. SO ₂	14-17	100 (compared with 1929 fresh)
	All unsulphured products	up to 72 gm. tried	0

the dried product. Morgan and Madson² showed that the vitamin A activity of this fruit is almost exactly commensurate with its carotene content, a fact also noted by Brockmann,⁴ who stated that the apricot is the richest vegetable source of this provitamin. The vitamin A of dried yellow peaches is quite uniform almost regardless of preparation, and that of prunes is only slightly affected, the unsulphured prunes retaining about 30 per cent less vitamin A than do the sulphured. However, in commercial practice sulphured prunes are but little in use.

Quite similar but as yet unpublished data have been accumulated with reference to Thompson seedless raisins¹⁰ and 4 varieties of figs.¹¹ Dehydration has been found definitely more favorable to vitamin A retention than sun-

drying, and sulphuring in nearly all cases is an additional protective factor.

FIGURE I—Average weight curves of guinea pigs fed sulphured and unsulphured dried apricots as sole source of antiscorbutic vitamin. The daily doses are given opposite the curves. Four to 10 animals were used for each dose.

Grapes like apricots are peculiarly subject to oxidative changes, and only dehydrated raisins were found to retain significant amounts of vitamin A. Only the dark Mission figs are well endowed with this vitamin and the sulphured product retains a significantly larger amount thereof than the unsulphured, 31 as compared with 20 per cent. The variety, rather than the horticultural or drying conditions, was found to determine the provitamin A value of dates.⁷

2. Vitamin C is nearly completely lost in both sun-drying and dehydration except in the sulphured products.^{5, 6} Again the sulphured peaches were found most likely to retain the full antiscorbutic property of the fresh fruit, with sulphured prunes next and apricots least. Figures I and II represent typical experiments with sulphured and unsulphured fruit. As shown in Table III, the protective action of the sulphur dioxide was not apparent in apricots unless 470 p.p.m. were retained in the dried product.⁶ In no case was it possible to demonstrate a significant

amount of vitamin C in the dried figs, either sulphured or unsulphured, although in 3 varieties, Kadota, Calimyrna, and Adriatic, a fair amount is present in the fresh fruit.¹¹ Neither dehydration nor sulphuring was effective. There may be some unusually effective oxidative catalyst in this fruit. Similar results were found with the Thompson seedless grapes and raisins¹⁰ and no conclusions could be drawn about the preservation of the vitamin in this fruit because of its rapid destruction even in frozen storage and its low value in the fresh fruit. Dates also were negative as to vitamin C.⁷

Apparently nearly the same conditions hold for the preservation of vitamins A and C. Both are heat labile, readily oxidized and therefore protected by rapid relatively low temperature drying, that is, dehydration, and the presence of a reducing reagent such as sulphur dioxide.

3. Vitamin B has been recognized as distinct from G for only a few years. Our first systematic tests for the presence of this substance in fruits were

FIGURE II—Typical guinea pigs fed dried apricots as source of vitamin C. The animal on the left received 4 gm. daily sulphured apricot, that on the right 15 gm. daily unsulphured apricot.

TABLE III
VITAMIN B (B₁) CONTENT (BY RAT ASSAY) OF DRIED FRUIT AS AFFECTED BY SO₂

Fruit	Amount fed daily gm.	Number of rats	Initial (depleted) weight gm.	Final weight gm.	Gain or loss gm.	Period days
Unsulphured raisins	1.0	5	71	92	21	56
	1.5	26	59	93	34	56
	2.0	23	56	95	39	56
	2.5	9	74	116	42	56
Sulphured raisins	1.5	3	61	44	-17	22
	2.0	10	54	43	-21	28
	3.0	10	67	52	-15	30
Unsulphured dried peaches	1.0 or 2.0	9	64	49	-15	30
	3.0	5	78	67	-11	52
	4.0	4	69	114	45	56
Sulphured dried peaches	2.0 to 6.0	18	66	50	-16	20

made in 1931. Thompson seedless grapes and raisins were tested and it was expected that the sulphured products would show at least as good retention as the unsulphured. To our surprise almost complete destruction of this vitamin had occurred in the sulphured raisins, and quite good preservation, about 60 per cent of the original,

in the unsulphured or natural products (Table III). Similar although less clear-cut results were seen in the studies of figs, peaches, and apricots. Typical data on sulphured and unsulphured raisins examined for vitamin B activity by pigeon test are shown in Table IV.¹⁰ This outcome might have been predicted from the scattered suggestive

TABLE IV
VITAMIN B (B₁) CONTENT (BY PIGEON ASSAY) OF RAISINS
AS AFFECTED BY SO₂

No. of birds	Daily dose required for maintenance				Retention of Vitamin B of fresh fruit per cent
	Wheat germ alone gm.	Fruit		Equiv. in fresh fruit gm.	
		Type	gm.		
6	0.7-0.9	natural raisins	7	25	64
4	0.7-0.9	sulphured raisins	7 and 0.5 gm. wheat germ	76	21
3	0.7	fresh grapes	16	16	100

reports of the relative stability of vitamin B₁ to oxidation particularly in acid reaction. Its well known instability in alkaline solution is apparently not due to oxidative but to some other type of change. Protection by sulphur dioxide or other reducing agents could not therefore be predicted, but actual destruction under these circumstances was not expected. However, there are faint indications in the literature that reducing agents may break down anti-neuritic activity—for example, Levene and Van der Hoeven's finding⁸ that omitting hydrogen sulphide treatment of lead acetate saturated concentrates increased the amount of vitamin left in the filtrates. A parallel destructive effect was seen in a rice polish vitamin B concentrate treated with gaseous sulphur dioxide.¹⁰

On the whole, dried fruits are not a rich source of vitamin B, with the possible exception of unsulphured raisins and prunes. These 2 varieties are of about equal value, containing about 1 Chase and Sherman unit per gram.

4. *Vitamin G*—Our data as to vitamin G (B₂) are not adequate for the full evaluation of the effect of methods of drying. Apparently this substance is quite resistant to change and is therefore little affected by sulphuring, dehydration, sun-drying, or lye dipping. Prunes are the only fruit we have so

far tested which is sufficiently rich in vitamin G to allow a real estimation, and in this case only the commercial dried product has been used. A photograph is shown in Figure III of litter-mate rats after 7 months' test,¹² one without source of vitamin G, the other fed 2 grams of prunes daily as sole source of G.

Guha⁹ has reported recently that vitamin B₂ is not destroyed by sulphur dioxide, nitrous acid, hydrogen peroxide, ozone, nor long continued heating even under increased pressure, particularly at pH of less than 7.

The first 3 questions, namely as to the effects of sulphuring, dehydration, and sun-drying upon the 4 vitamins in various fruits, have now been answered so far as our data will allow. The fourth question, that of the effect of cooking, has been answered in detail for A and C in sulphured and unsulphured apricots.³ The same protective effect exerted by the sulphur dioxide upon vitamins A and C during drying was seen also in the open kettle cooking of the sulphured fruit (Figure IV). The loss of retained sulphur dioxide by the fruit during storage and cooking was found to be relatively great so that the product as eaten is likely to contain only traces. Commercial storage for 6 months at room temperatures and processing and re-sulphuring were found to

FIGURE III—Litter mate rats after 7 months on vitamin G free diet, the animal on the right having received in addition 2 gm. of prune flesh daily, that on the left no addition to the basal diet.

reduce the antiscorbutic value of the fresh fruit 50 per cent. No measurable reduction in vitamin A was caused by processing and resulphuring (Figure V).

The fifth question, as to the possible development of antirachitic activity in the sun-dried fruit, was considered in apricots and dates. Some of the dates had been sun-dried in Asia and some in California. Only traces of vitamin D were present in any of these dried samples⁷ and the sun-dried were if anything less active than the dehydrated. Another answer might be found perhaps if other samples were tested.

The sixth question, as to lye dipping, is easily answered. It was tested on prunes and raisins and the process as practised was found to be either inert or favorable to the preservation of

FIGURE V—Average weight increases of rats fed 22.5 mg. daily of raw and cooked dried apricots as source of vitamin A; sulphured sun-dried, S2; unsulphured, sun-dried, S3; processed, sulphured, sun-dried, S4.

vitamins A, C, and B.^{5, 6} The A and C of lye-dipped prunes were better protected by subsequent sulphuring than were the undipped, and the lye dipped raisins were somewhat better sources of both A and B than the otherwise similarly prepared but undipped fruit. The effect may be in the direction of increasing digestibility in the unsulphured fruit and increasing penetration of the protective sulphur dioxide in the sulphured fruit.

No sweeping statements can be made about any of these drying methods, because the nature of the fruit and of the vitamin concerned provides a different set of conditions in each case. Vitamin A is most adversely affected by sun-drying, particularly in apricots and raisins; it is favorably affected by sulphuring and by lye dipping. Vitamin C is largely destroyed in all fruits by any form of drying unless sufficient sulphur dioxide is present, and in that case also perhaps in figs and raisins. Vitamin B (B_1) is adversely affected by sulphuring, but less so by sun-drying than the other vitamins. Vitamin G is apparently indifferent to all the processes involved, but except in prunes is not found in notable amounts in either the fresh or dry fruits so far studied.

FIGURE IV—Average growth curves of guinea pigs fed various quantities of raw and cooked sulphured, dried apricots, S2 and raw, unsulphured apricots S3 as source of vitamin C.

What practical advice may be offered therefore to the producer and consumer of dried fruits? Obviously each fruit must be considered on its own merits and prepared by that method which will retain the largest proportion of its best natural endowment. Peaches and apricots should be dehydrated and sulphured to retain their excellent natural content of vitamins A and C, even though their small B content be largely lost. Raisins should not be sulphured but should be lye-dipped and dehydrated to preserve their good vitamin B and A content, and should not be counted on for vitamin C. Prunes should be lye-dipped, not sulphured, and dehydrated also since their natural endowment is similar to that of raisins. Figs which are not rich in either A or C should be unsulphured and either dehydrated or sun-dried. The black Mission figs however contain enough vitamin A to merit dehydration.

Rapid Growth

. . . The philosophy which dominates the field of nutrition assumes that a young animal which grows rapidly is the ideal for maximum health both during the growing period and during adult life. This philosophy has developed under the influence of several stimulants. . . .

A third stimulus whose importance may be overlooked is that of commercial advertising. While preparing this note I selected at random one of the copies of the *Journal of the American Medical Association*, which is published weekly. More than a fifth of the advertising in this journal was devoted to fortified foods for children, chiefly for defenseless babies that are more or less easily coerced into engulfing various vitamin concentrates. It must

be possible to market such products. Who can estimate the effectiveness of such constant advertising in the journal of the American physician in creating and moulding his philosophy and his recommendations in feeding children? Is it any wonder that the pediatrician has become an advocate of rapid growth? Even the manufacturer of scales does his part by buying space in this same professional journal in order that no one shall neglect to keep his child up to date in weight. Thus has been created an enthusiasm for growth and growth stimulants. And what profit in dollars can be made from any other philosophy?—Dr. C. M. McCay and Mary F. Crowell, *Prolonging the Life Span. Scient. Month.*, Nov., 1934, pp. 405–406.

Beverage Bottling and Beer Dispensing^{*}

Covering the Everyday Problems of the Sanitary Inspector

F. E. DEGROFF

Beverage and Bottling Division, City Health Department, Los Angeles, Calif.

THE general term "bottling" includes not only glass bottles but every other container used for beverages. If new containers were used entirely there would be few problems for the sanitarian. The unfortunate practice of re-using bottles, and the source from which the second-hand bottles come, are matters of great importance to the bottler and to the public. Cleanliness and sterility of the container is necessary for the prevention of spoilage and the preservation of flavor and color of the beverage. With carbonated beverage, beer, and water bottlers, the containers are usually returned to the plant from which they came within a short time and seldom put to any other use. With wine, ginger ale, lime rickey, and several other beverages, plain bottles are used with no identification marks and no regular method of return, and these are often put to other uses.

In bottles that have been picked up by junk collectors, liquids of almost every description are found, such as oils, paint, chemicals, and drugs, often with flies and other insects, and dirt dried so hard that ordinary washing methods fail. As these bottles are returned

ultimately to some bottling plant, cleansing and sterilizing becomes of utmost concern. The larger bottling plants having mechanical equipment with the use of caustic, high temperature, sufficient time for soaking, adequate rinse, and close inspection to remove any dirty bottles, are able to obtain clean sterile containers. Even in these plants the effort to cut down manufacturing costs frequently causes them to be careless in maintaining proper caustic balance, correct temperature or renewing solutions.

The bottling trade, and the health authorities also, are much indebted to the research work of the Association of the American Bottlers of Carbonated Beverages through the Fellowship maintained at Ames College, in obtaining a standard washing formula. Legislative bodies in many states, counties, and cities have adopted the A.B.C.B. code as a law governing beverage bottling. Briefly, this requires a $2\frac{1}{2}$ per cent caustic solution at a minimum of 120° F. for a period of not less than 5 minutes. Variations from this standard may be made where a higher temperature, more caustic, or a longer soak is used. As the object is a clean, sterile bottle it is not so important that the law be followed to the letter; but in case of failure, the fact that there has been a violation of the legal requirements places a strong weapon in the

^{*}Read at a Joint Session of the California Association of Sanitarians and the Public Health Engineering Section of the American Public Health Association at the Sixty-third Annual Meeting in Pasadena, Calif., September 4, 1934.

hands of the inspector to enforce compliance.

In the smaller plants, and where large bottles such as gallon and 5 gallon demijohns are handled, and machine washing is not used, hand washing with a brush and a good cleansing solution in tepid water followed by a thorough rinse with clean water, then immersion in a chlorine solution of not less than 50 p.p.m. of available chlorine, will give satisfactory results.

The essential points of plant inspection are: location of building—free from objectionable surroundings, of substantial construction, thoroughly rat-proofed and screened from insects; floors to be of cement or material impervious to moisture and sloped to a drain; rooms for preparing syrups, etc., to be separate; employees to be clean in person and habits. Samples for bacteriological examination should be taken of the water supply before and after filtering or treating, and after carbonation to locate sources of contamination. Tests for sterility of washed bottles should be made frequently. The inspector should be equipped to make tests at the plant for caustic content of wash solution, for presence of alkali in the rinsed bottle, and for the amount of available chlorine where this method of sterilization is depended upon.

It is important that the operators provide for the inspection of the bottles before they are filled and of the finished product to detect the presence of any foreign substances. In spite of all precautions, many specimens have been found on the market, or have been brought by the public to the attention of the health department, containing clothes pins, rusty nails, rubber brush tops, hairs from brushes, flies, spiders, broken glass, cork, varnish, and many other foreign substances.

Wine bottling at the winery, liquor bottling at the distillery and rectifiers or at the bonded warehouse, need little

attention, as new glass is invariably used. Many practices and methods used in wine and liquor manufacturing should be discouraged, and by the tactful suggestion of the inspector much improvement may be made.

Beer bottling at the brewery is also well taken care of with adequate equipment. However, many small concerns attempt to bottle beer, shipped in bulk to lessen transportation costs, without adequate equipment for cleaning, old bottles invariably being used with hand operated filling and capping devices. Unless there are regulations prohibiting, this will lead to many difficulties for the sanitary inspector and many complaints of spoilage from the public.

Oranges are probably the hardest of all fruits from which to obtain a fresh juice for beverage purpose without contamination by bacteria and molds from the peel. To wash in a cleansing solution with brushes, to rinse, sterilize, and dry before cutting, seems the only solution. This requires expensive equipment, time and labor, bringing the cost to a point where competition by less conscientious operators makes it prohibitive. Only by the adoption of state-wide laws can any degree of perfection be expected.

Under the present code regulations it is impossible for the fresh fruit juice manufacturer to buy fruit from the packing-house at by-product prices. This forces him to patronize peddlers who buy from growers outside the Association, consequently he gets culls of poor quality, scale infested, not processed, many picked from the ground where there is the possibility of contamination from the fertilizers used. Reports show excessively high plate counts, often *B. coli* and invariably molds. Only by the washing process can this be avoided. Such juice is usually put up in milk bottles with paper caps. The bottles and filling equip-

ment should be handled as in milk plants, by methods well defined in laws and ordinances covering the dairy business.

Sources of trouble in plants may be enumerated as follows:

Bottled Water Plants—Springs and wells—covering to prevent entrance of flies and other insects and birds, protection against rodents and other animals, overflow pipes to be so arranged as to prevent any possibility of back flow or flooding, methods of handling corks, sterilization of filling taps, regularity of reconditioning water filters.

Breweries—Rodent infestation around the grain and malt storage buildings and outbuildings, drainage and facilities for

flushing, loading platforms or rooms, frequent removal of all waste materials.

Grape Presses and Wineries—Disposal of waste, protection from and extermination of flies, ventilation of wine fermenting and storage rooms, floor drainage and methods and means for cleaning presses and vats.

BEER DISPENSING

The repeal of the 18th Amendment has changed the conditions covering the dispensing of drinks at soda fountains and restaurants and added beer parlors to the already numerous places for dispensing beverages. By efforts of the Health Department the methods of washing glasses and

GLASS AND DISH WASHING REPORT

dishes has been brought to a very high standard through the use of hot water, soap or other cleansing materials, and a hot-water rinse. In serving beer in large and heavy glasses, frequent breakage and also the desire to have a cool glass have caused the dispensers to discard the use of hot water.

This has caused a falling off in the standards for all glass washing. The report on glass and dish washing methods obtained through inspection by extra men allotted through one of the S.E.R.A. projects, is as follows: Water

was classified as "hot," being 120° or too hot for the hands; "warm" between 100 and 120°; "tepid" below 100°; and "cold" as drawn from the faucet, being below 70°.

Following this report surprise inspections were made by regular inspectors; temperatures were observed; and samples were taken. It was found that in a few instances temperatures above 100° were being used; often there was no cleansing agent; glasses were being dipped in cold water, then in a cold rinse, and the wet glasses used without

being drained. Laboratory reports on wash and rinse waters in practically all cases showed a bacteria count in the millions with a positive *B. coli* index. Following these reports numerous arrests were made and convictions obtained.

The report on samples taken at the time of arrest is shown in Table I.

Note the results on samples taken with regard to the sterilizing agent used in wash or rinse water in Table II.

It will be noted that where a chlorine content of even as low as 15 p.p.m. was used, the bacteria count was 0 or very low, and where cleansing agents with no chlorine were used, the count was invariably high, with often a positive *B. coli* index.

From these reports, in addition to thorough washing in a cleansing solution, a chemical sterilizer should be required where live steam is not available, even in the case of mechanical dish washing machines. The practice of refilling glasses is objectionable and should be prohibited, because glasses are often mixed and do not reach the original user and also because the beverage drying on the glass will often affect the taste and appearance when refilled. The used glass may contaminate the faucet through the foam while being filled as it rises above the top and over the faucet.

A cooling bath (after cleansing and

sterilizing during which glasses are immersed in ice water until used) is especially to be discouraged, as tests have shown this water to be teeming with bacteria. A dry chill cabinet should be provided. Wiping of glasses with a towel is bad practice and brewery interests recommend serving beer in a wet glass. Beer when delivered in barrels should be immediately placed under refrigeration and kept at a low temperature until served. While beer distributors usually maintain a coil cleaning service, the inspector should know that such cleaning is regularly practised. Adequate toilet facilities for both sexes should be required and well maintained.

The coöperation of the brewer, restaurant and other trade associations should be solicited to raise the standard of dispensing beverages at this time as the trend is in the opposite direction, and unless earnest effort is made practices will be established which will undo much of the good that has been accomplished through years of work.

Referring again to bottling and the use of reclaimed or second-hand glass bottles or containers of any kind for any food products, legislation to prohibit their use unless washed and sterilized by standard methods, and to license dealers only when approved equipment is installed, should be urged.

Public Health Degrees Granted in 1934*

THE following tables similar to those published in previous years present the data concerning students registered in schools of public health, and the public health degrees granted in the calendar year 1934.

Isolation of Streptococci from Milk*

WILLIAM M. GROESBECK

Hornell Branch, Steuben County Laboratories, Hornell, N. Y.

THE isolation of streptococci from milk frequently becomes a problem due to the presence of other bacteria. Provided that the material has been collected with the proper aseptic precautions the isolation is readily made from individual cow specimens, but in examining composite samples from producers' cans prior to pasteurization, or herd samples, the development of streptococci is often obscured by the luxuriant growth of other microorganisms.

There are several means of isolation: simple dilution of the sample, the addition of a substance to the milk to prevent growth of undesired flora prior to the cultural examination and the use of differential media.

Dilution of the sample often results in the loss of the streptococci before the extraneous bacteria become sufficiently few in number to allow the former to be detected. The use of glycerol to form a 30 per cent solution with the milk, as has been recommended for the preservation of members of the *abortus-melitensis* group,¹ has been found to be applicable also to streptococci.² Brilliant green and gentian violet have been used successfully for the same purpose.³ The great advantage in the use of these substances is that the samples may be sent through the mail exposed to room temperature without an appreciable altering of the results. By using a differential medium,⁴ an interpretation based upon the

number of colonies of streptococci present may be obtained. Such a medium usually depends upon its dye content for the inhibition of the undesired flora, and since the bacteriostatic action of dyes is often irregular the efficiency rests largely upon very careful standardization of the dye content of each lot prepared. For a similar reason it is essential that the final dilution of a dye be correct when it is added to a milk sample.

In a laboratory where a small staff and limited facilities for media making are important factors the preliminary treatment of milk samples with sodium carbonate, followed by the isolation of the streptococci upon routine blood agar,⁵ has been found to give excellent results. A 1 per cent solution of sodium carbonate has been used by other workers⁶ when only the streptococcal content of feces were desired. Adapting this technic to a similar procedure for milk, the following method has been found to be most satisfactory when composite samples or herd samples are to be examined for the presence of streptococci.

One c.c. of a thoroughly mixed sample may be used. Preferably, however, the gravity cream is removed and 1 c.c., emulsified in a test tube containing 10 c.c., of a freshly prepared sterile 1 per cent solution of sodium carbonate of tested purity. In the original method as applied to the examination of feces incubation at room temperature for 24 hours is recommended. It has been noted that if the milk-sodium carbonate mixture is placed in an incubator at

* Originally presented at the mid-year meeting of the New York State Association of Public Health Laboratories, Albany, N. Y., November 4, 1932.

37° C. overnight, growth of the streptococci (if present) occurs and Gram negative bacilli are destroyed. Following this procedure sub-cultures from the carbonate solution are made upon blood agar plates and the isolation completed in the usual manner.

Palo Alto Annual Report

BY the middle of February the Health Officer of Palo Alto, Louis Olsen, has released copies of his 24 page annual report for the calendar year 1934. Last year this city won first award in its population class in the Health Conservation Contest sponsored jointly by the U. S. Chamber of Commerce and the American Public Health Association.

Palo Alto is spending \$.93 per capita in its Health Department, the appropriation of which represents 3.6 per cent of the city budget. In this college town of 15,900 population there were no resident deaths from diphtheria nor

any of the other common communicable diseases. The Health Officer states that his diphtheria immunizations are done under a uniform plan followed in Santa Clara County, whereby the family physician does the immunization for a nominal sum and the Health Department furnishes the material.

In 1934 poliomyelitis was a problem on the Pacific Coast. There were 6 cases reported in Palo Alto with no death. There were reported 127 deaths from all causes in the city with a rate of 8.0. The birth rate was 10.9 which is below the 10 year average of 11.6.—H. F. V.

A Central Information Service on Current Practices of Health Departments*

JOSEPH W. MOUNTIN, M.D., F.A.P.H.A.

U. S. Public Health Service, Washington, D. C.

THE present economic depression and the attending changes in social philosophy have accelerated the adjustments in budgets and programs of health departments which normally occur in a more orderly fashion. Health administrators, more than ever before, feel the need of current information on the status and practices of health departments throughout the nation as a guide in meeting their local situations. Strange as it may seem, there has never been developed in this country any comprehensive national system for reporting data of special interest to health officials, other than morbidity and mortality. Attempts at collecting more extensive information on health administration so far have usually taken the form of periodic cross-section surveys,† except for those county health departments which are required to report to state and national contributing agencies. The U. S. Public Health Service has required fairly complete reports from county health departments to which the Service extends financial assistance, and much of the data derived in this manner

are presented annually in the *Public Health Reports*.

It is accepted as a principle by the Committee on Administrative Practice that a comprehensive system of reporting to be effective and permanent must eventually become a function of an agency in the federal government which is equipped for collecting data of this type and making the findings available. Pending the establishment of such a national reporting system, the committee felt that the resources of the American Public Health Association might be utilized for preparing the way and determining the types of information which could be obtained with relative ease and yet meet the more urgent needs of health officials. A special sub-committee, known as the Sub-Committee on Current Practices of Health Departments, was therefore appointed for the purposes just indicated.

A preliminary study was made to find a few summary measurements which would express activity and at the same time supply data for answering the more common inquiries. In analyzing the inquiries received from health officials, it was found that the information desired most frequently related to health department budgets. Next in the order of frequency were questions concerning personnel. It was also found that, when figures on budgets are extended to in-

clude amounts allocated to different services, and when personnel are reported by professional classes and time devoted to duty, these simple data constitute reliable indices by which to judge progress or retrogression over a period of years. Information on services is extremely desirable, but the collection of such data from health departments and the analysis would add materially to the cost. Furthermore, its value may be questioned since there are no generally accepted definitions for activities and no standard method for recording or reporting service items of health departments. It therefore seemed best for the present at least to concentrate attention on data pertaining to funds and personnel, and to begin the formulation of definitions which might be used later in the recording and analysis of service items.

Fortunately, data on funds and personnel meeting the requirements just set forth come to the office of the American Public Health Association each year, in connection with the Inter-Chamber City

Health Conservation Contest.* The schedule used in connection with the contest also provides for reporting a limited number of services common to health departments, but these are not being studied by the Sub-Committee on Current Practices of Health Departments at the present time.

CENTRAL OFFICE RECORDS

It must be understood that the primary purpose of this sub-committee is to assist in the development of a central agency for collecting and recording up-to-date information on health departments which might be of use to persons occupying administrative positions in health agencies. In connection with this basic function, a summary card file (Figures I and II) is kept current in the office of the American Public Health Association for all cities in the Inter-Chamber City Health Conservation Con-

* The contest was extended in 1934 to counties and rural districts having organized health departments

test. It is the expectation that the number of reporting cities may be increased by other means in addition to the contest. The hope is expressed that the Sub-Committee on Current Practices of Health Departments may find its greatest field of usefulness in supplying information direct from its files to health administrators. While publication of data is only incidental to the main purpose, which is recording, certain summary reports will be issued from time to time.

A preliminary review was made of the data collected through the contest to determine changes in size of budget occurring during the years 1930, 1931, 1932, and 1933. The remainder of the report will be devoted to a presentation of a few findings.

EXPENDITURES BY OFFICIAL AGENCIES

Total and per capita expenditures through official health agencies are given in Table I. Included in this table are expenditures through official health agencies for services other than hospi-

talization, institutional care, medical relief, garbage collection and disposal, capital outlays and deficits. Expenditures by boards of education for medical and nursing services are included also, but not expenditures for physical education and health instruction. In brief, the expenditures are for services constituting the generally accepted public health program of most urban communities. These services were: administration, vital statistics, general sanitation, control of food, drugs, and milk, child health supervision, communicable diseases, tuberculosis, venereal diseases, and laboratory. Inasmuch as some cities appear in each of the 4 years of the contest while others may be entered for 1, 2, 3, or 4 years, direct comparisons of figures for 1 year with those of another therefore must be made with due caution. Furthermore, the number of small cities is not sufficient to constitute a reliable sample. Notwithstanding the shortcomings in the basic data, it seems entirely proper to make certain general observations regarding the adequacy of

funds for health services and the variation in amount from year to year.

There is a remarkable uniformity in the average per capita expenditure of the cities in all groups. Group I reports the highest expenditure; Group IV, next; and Group VI, the lowest; but the differences are very slight. The picture changes, however, if maximum and minimum expenditures by different groups are compared. While the spread between the two extremes is marked for all groups, both the highest and the lowest per capita expenditures are reported by the small cities in Groups V and VI. Attention, however, is again called to the small number of cities in the latter groups and the consequent unreliability of the sample. There also appears to have been some selection of cities in Groups V and VI with large per capita expenditures, thus distorting to some extent what is probably the true

situation for these groups as a whole. In this connection, it may be well to mention the fact that a small city reporting a high per capita budget may still have an inadequate service since fixed charges for even a minimum health organization, when distributed over a small unit of population, are certain to result in high per capita expenditures.

While the figures presented in Table I are based on accumulated totals for different cities each year, it would seem that appropriations either continued to increase or remain stationary through 1931. Some drop in appropriations occurred in 1932, but the fall was very decided in 1933. By internal economies, the health departments probably were able to compensate for the small reductions made prior to 1933, but in that year it is apparent that there must have been serious disorganization of staff and consequent impairment of

TABLE I

A COMPARISON OF TOTAL AND PER CAPITA EXPENDITURES FOR HEALTH SERVICES *
BY OFFICIAL AGENCIES † FOR THE YEARS 1930, 1931, 1932, 1933

Group	Year	Number of Cities Reporting	Population Represented	Total Expenditures	Average Per Capita Expenditure (In Cents)	Maximum Per Capita Expenditure (In Cents)	Minimum Per Capita Expenditure (In Cents)
I—500,000 and over	1930	9	8,681,122	\$7,304,295.38	84.1	117.1	41.5
	1931	8	10,173,557	9,767,642.27	96.0	125.2	61.0

TABLE II

NUMBER OF CITIES SUBMITTING SATISFACTORY DATA FOR TERMINAL YEARS
OF PERIOD 1930-1933

<i>Group</i>	<i>Number of Cities Accepted 1930</i>	<i>Number of Original Cities Accepted 1933</i>
I—500,000 and over.....	9	7
II—250,000 to 500,000.....	16	8
III—100,000 to 250,000.....	26	14
IV— 50,000 to 100,000.....	28	12
V— 20,000 to 50,000.....	40	10
VI—Under 20,000 . . .	53	9

service in some places at least. Other information coming to the attention of the committee suggests that this was the actual condition of affairs.

Sixty cities entered in the contest filed satisfactory reports for the terminal years 1930 and 1933. The figures were analyzed for the purpose of determining possible changes in the amount of funds available for health services studied in connection with this report. The figures for the large cities are considered more significant than those for the smaller cities because more cities of the larger population groups enter the contest and more continue to submit data acceptable for analysis. Figures substantiating this point are given in Table II. For example, 7 of the 9 original contest cities in Group I also presented acceptable data for the year 1933, but the small number of original entries and return cities in the lower population groups renders the sample extremely unreliable for statistical analysis. This again emphasizes the difficulty which is always encountered in trying to obtain information on any large number of cities below 50,000 inhabitants, and to some extent the same statement is true of cities up to 100,000 inhabitants.

The expenditures of the 60 cities filing acceptable data for both 1930 and 1933 are shown in Table III. These figures include expenditures through official health agencies for services other than hospitalization, institutional care, medical relief, garbage collection and

disposal, capital outlays and deficits. Expenditures by boards of education for medical and nursing services are included also, but not expenditures for physical education and health instruction. A very material decrease in appropriation was experienced in 1933 as compared with 1930. The percentage reduction varied from around 25 per cent in Groups I and II, to 10 per cent in Group IV. In the other three Groups—III, V, and VI—the percentage reductions were 17.3, 13.4, and 15.5, respectively. According to Table I, to which reference has already been made, 1931 seems to have been the peak year from the standpoint of expenditures for health by cities in Groups, I, II, and III. Consequently, if expenditures for 1933 had been compared with 1931, the percentage reductions might have been considerably more. In Group II, there appears to have been some selection of cities reporting low per capita expenditures for the terminal years; otherwise the cities included in Tables I and III seemed somewhat comparable. Direct comparisons, however, between the figures given in Tables I and III must be made with due caution because the same cities are not under consideration in each case. No reason can be given for what appears to be an excessive curtailment of expenditures in the large as compared with the smaller cities. It may be said in extenuation, however, that the larger cities perhaps were in better position to adjust themselves to reduced budgets by simply lessening the

TABLE III

	1933	10	342,091	303,956.96	88.9	13.7	13.4	166.5	21.7
VI	1930	9	114,720	76,126.51	66.4	181.6	27.2
	1933	9	114,720	64,338.69	56.1	10.3	15.5	189.6	23.7

* Exclusive of hospitalization, institutional care, medical relief, garbage collection and disposal, and capital expenditures and deficits.

† Includes Board of Education expenditures, but not expenditures for physical education and health instruction by teachers.

service, whereas the same percentage reduction in budgets of smaller cities would mean wholesale dismissal of personnel including those holding key positions on the technical staff. On the other hand, it is a source of considerable discouragement to learn that the expenditures in cities of Group II have fallen to 58.6 cents per capita which is below the figure (59.01 cents)* reported for the largest cities in 1923. Thus the goal \$2.00 per capita per annum recommended by the Committee on Administrative Practice appears to be receding, for the time being, at least.

SUMMARY

The Committee on Administrative Practice of the American Public Health Association as well as its precursor, the Committee on Municipal Health Department Practices, is deeply concerned in making available information relative to the status and practices of state and local health departments. Most of the data published so far are of the cross-section survey type assembled at in-

tervals of from 5 to 10 years. Such surveys have furnished valuable information, and should be repeated as the occasion demands, but information less detailed in character should be kept current.

A special Sub-Committee on Current Practices of Health Departments was formed to study the types of data required for answering most inquiries and the feasibility of developing a national reporting system. Schedules assembled in connection with the Inter-Chamber City Health Conservation Contest were made available for study purposes. The Sub-Committee on Current Practices of Health Departments is of the opinion that information collected on an annual basis covering expenditures by purpose, and personnel by professional classification should furnish sufficient data for answering most of the inquiries and serve as a basis for estimating progress or retrogression. The collection of such data on a nation-wide basis should not involve any great difficulty or large expense if made a routine activity of the U. S. Public Health Service. Information on services is to be desired, but its collection and analysis does not seem feasible until clear-cut definitions for

* Municipal Health Department Practice for the Year 1923, *Public Health Bull.* 164, Government Printing Office, 1926.

specific services and standard methods of reporting can be established.

From a preliminary analysis of the data assembled through the contest for the years 1930, 1931, 1932, and 1933, it appears that appropriations were maintained through 1931; in 1932 some reduction occurred; but a drastic cut was made in 1933. Budgets are rapidly approaching those reported for 1923 in *Public Health Bulletin* 164.

Lead Poisoning in Czechoslovakia

THE Czechoslovak Ministry of Social Welfare has recently circulated to the other departments a draft Bill for the purpose of excluding women and young persons under 18 from employment in certain processes in the treatment and handling of lead and zinc. The Bill also lays down certain conditions to be observed in regard to the employment of adult male workers in such processes:

The operations from which women and young persons under 18 are excluded are those enumerated in the Lead Poisoning

(Women and Children) Recommendation, 1919, and the restrictions to be imposed relative to employment of adult male workers in these processes are those prescribed in the Recommendation for women and young persons where their employment is permitted in processes involving the use of lead compounds, with the addition of more detailed requirements as to the state of the workrooms, lighting and ventilation, methods of cleaning and protective clothing.

The Bill also provides for medical examination on engagement and rejection of the unfit.—*Indust. & Labour Inf.*, LIII, 5 (Feb. 4), 1935.

SHALL MARRIAGE COUNSELLING BECOME AN AMERICAN PUBLIC HEALTH FUNCTION?

BY marriage counselling we understand such advice by medically trained persons, and others with legal and social or psychological competence as is sought by men and women, unmarried or married, who believe that their lives together will be happier and wiser if they learn, before rather than after they have met conflict and suffering in marital sex relations, what medical and social experience has gathered and can legally impart to them. By the term "public health function" we refer to the authorized and tax-supported use of official health agencies under the police power of the states or under federal government, for the promotion of health, the prevention of sickness, and the postponement of death.

From Aroostook County, Me., to Los Angeles, Calif., physicians, nurses, and health officers are engaged in the preliminary experiences with their communities, with religious sects, and with appropriating bodies of local government in the matter of contraceptive advice.

There are now in operation in the United States, including Hawaii and Alaska, 157 marriage advice centers, of which 18 are controlled and served by the local public health authority. Twenty-six of the states have one or more of such centers, and in the case of 4 (Michigan 12, Pennsylvania 19, California 29, and New York 32), they are numerous and fairly distributed according to population. Thirty-five of these stations of medical and health information are in hospitals, the remainder being apart from any agency for the organized care of the sick.

Up to the end of 1934 not less than 200,000 women have sought and received advice at such centers, or 1 for each 100 women of childbearing age in the population. The ratio of marriage advice stations to population is one to each 400,000 in New York City.

The 3 stations in the rural area of Aroostook County, Me., established since August, 1934, with the approval and financial assistance of Town Managers and Selectmen, with the endorsement of the local medical profession, and associated with home visits by the district nurses, served 161 patients in the first 10 weeks.

The issuance of *Circular No. 1408*, May 31, 1934, by the Ministry of Health of Great Britain to Local Health Authorities, constitutes the latest episode in a history of progress in liberal social use of medical knowledge, beginning with the activities of the Malthusian League (1877-1914), and carrying on through the Women's Coöperative League (1923); the memorandum of the Ministry of Health (1924); Dame Janet Campbell's *Report on Maternal Mortality*, 1924; a resolution of the House of Lords favoring distribution of birth control advice among the masses (1926); approval by the Bishops of the Church of England of birth control (1930); the memorandum No. 153 M.C.W. by which the Ministry of Health allowed local health authorities to furnish birth control information to women attending local child and maternal welfare centers (July, 1930); and the *Final Report of the Departmental Committee on Maternal Mortality and Morbidity* (1932), which specifically recommends the giving of contraceptive advice to women on certain medical indications.

The latest circular (No. 1408) carries into effect by the option of the local health officer, and by public funds, the opinion of the Ministry of Health, that it is proper to offer contraceptive advice to married women suffering from illnesses which are detrimental to them as mothers, discretion as to what is or is not medically detrimental being left to the physician in charge of the clinic.

Careful, thorough, progressive, democratic, competent English leadership in the field of public health has in this matter included birth control information as an approved function of clinics devoted for many years past to practically all other phases of maternal and child health guidance.

In Germany, first in 1905, in voluntary agencies, and later in health offices, schools, hospitals, and churches, marriage counselling has been undertaken by the coöperative skill and training of physicians, lawyers, and persons with social and psychological training.

Evidence of the socially eugenic effect of the educational and technical service offered at the marriage advice bureaus of Germany, appears in the changes in the birth rates of 4 economic classes, for instance in Bremen, from which city the following data are obtained:

	<i>Birth Rate per 1,000</i>		<i>Per Cent Change</i>
	<i>1901</i>	<i>1925</i>	
Among families of the well-to-do	12.7	14.7	+ 15
Among families of the middle class	28.9	14.2	— 51
Among families of laborers	43.7	19.5	— 53
Among families of the poor	46.2	18.9	— 60

It would appear that the less competent but usually more prolific fraction of the population reduces its birth rate more than do the economically more favored groups. Similarly in France where contraceptive information has long been generally available, without legal sanction, there is a tendency of birth rates among all classes to approach equality.

	<i>1906</i>	<i>1930</i>	<i>Per Cent Change</i>
Birth rate among well-to-do in France	12.3	16.3	+ 32.5
Birth rate among the poor in France	22.9	16.6	— 28.3

With a marriage rate in the United States today of about 8 per 1,000, with 1 in 6 marriages ending in divorce, with at least 1 abortion for each 3 pregnancies, with 15,000 maternal deaths a year from criminal abortion, and a large amount of maternal mortality related to conditions in one or both parents of a preventable character, and with disproportionally high birth rates among the less competent

part of our population, we may well consider whether there are not lessons for us to learn and apply in the example of some European nations which, like England, Germany, Holland and the Scandinavian countries, have incorporated the protection of women against pregnancy by appropriate medical advice in their public health services.

Federal laws of the United States today forbid transmission of contraceptive information through the mail, even the addresses of marriage advice stations, or transportation of supplies for contraceptive purposes by express companies or other common carriers, or possession of articles intended for contraceptive purposes. The archaic laws of 1873 include contraceptive advice under the head of obscenity. Federal laws conflict with the state laws. Physicians legally giving contraceptive advice in a state have to bootleg supplies and educational material for their patients or go without. Commercial exploitation of fraudulent materials and measures is widespread.

The bugaboo of religious intolerance of medical advice for contraceptive purposes can no longer be honestly quoted in the face of publicly declared positions of a number of important organizations* which have expressed a favorable attitude toward the dissemination of birth control information under appropriate conditions.

It would appear that the public health profession in the United States has not only an opportunity but an obligation to make available through prenatal conferences, in maternity and baby and child health centers and through appropriate educational channels, under strictly medical control, such advice and guidance, including the teaching of safe and effective methods of contraception, as will preserve the physical and mental health of the family and in particular of the mother of living children. If there were no other good reason for the educational service of a marriage advice bureau, the necessity of warning women against the mechanical and chemical damage of many of the exploited and untrustworthy contraceptive devices should suffice.

The medical profession and the officers of health throughout the nation should be relieved of personal and official embarrassment in meeting their professional obligations, by repeal of much or all of the existing prohibitory federal and state laws affecting the giving of contraceptive advice, which at present are either disregarded or remain in disrepute and contribute to dishonesty, confusion of conduct, and commercial fraud.

Contraceptive clinics and marriage advice bureaus will doubtless continue to increase in number and patronage. It would be wiser to direct the demand toward professionally competent official agencies than to permit expansion and exploitation through those less qualified.

National Board, 1934.

LETTER FROM GREAT BRITAIN

THE RETURN OF PROSPERITY

The press here for some time has been announcing that trade and everything else is better, and the fact that the income tax was reduced may be taken as evidence. More definite evidence has been the prodigality in entertainments during the later months of 1934, and the extraordinary density of the shower of greeting cards and gifts that fell upon practically everyone round about Christmas time.

So far as entertainments were concerned, even members of the public health service were affected. The annual dinner of the Society of Medical Officers of Health itself, for example, appeared more lavish than usual, if in nothing else in the matter of speeches at any rate. To an extent this was because the occasion was chosen for having certain members as guests of honor, on account of the value of the services rendered to the society, its members, and the health service generally. Prominent among these guests was Dr. George F. Buchan, well known to public health workers in the United States as an Honorary Fellow of the American Public Health Association and for other reasons. The toast of the guests of honor was proposed by Sir John Robertson, Professor of Public Health in the University of Birmingham and formerly Medical Officer of Health of that city.

On the evening following the dinner there was a reception to, among others, representatives of the Society of Medical Officers of Health at the Hall of the Society of Apothecaries. This was something in the nature of an event and a very great honor, and was accorded largely because the Master of the Society of Apothecaries is Sir George

Buchanan, until recently Senior Medical Officer at the Ministry of Health.

The Society of Apothecaries is one of the City of London Companies, being an off-shoot of the Grocers' Company, one of the most ancient, wealthy, and prominent of these institutions. Practically all of these companies concern themselves with education in some shape or form. The Grocers' Company, for example, has endowed a school for boys, and annually grants a number of scholarships for medical research. The Apothecaries Company is, naturally, interested in medical education, and in addition to granting qualifications to practise medicine, following examination, also examines candidates for and grants special qualifications in obstetrics and gynecology. The Hall of the Society is one of the old buildings of the City and includes a number of interesting apartments in addition to the beautiful Hall itself, which is used for, among other purposes, banquets—invitations to which are greatly valued—receptions and so on. The Society possesses many pictures and much furniture, plate, and relics of great intrinsic value and immense historical interest. Also they have a very fine cellar and recipes for special beverages dispensed on important occasions such as this of which I write, when Sir George Buchanan, supported by his "wardens," Sir William Willcox, the well known medical jurist, and Dr. Fairbairn, Chairman of the Central Midwives Board, received members of the public health service as guests.

PUBLIC HEALTH REPORTS

With the appearance of Sir George Newman's *Report on the Health of the*

School Child, early in December, was completed the series of government health reports for the year 1933, in which health officers are particularly interested. The others are, of course, the report of the Ministry of Health, which always comes first, and the report *On the State of the Public Health*, which is Sir George Newman's report as Chief Medical Officer of the Ministry of Health. In *The Health of the School Child*, he reports as Chief Medical Officer of the Board of Education, the first government post, by the way, to which he was appointed. The report of the Ministry of Health covers a review of the whole field of work operated by the department, the subjects dealt with falling under the main heads of Public Health, Housing and Town Planning, Local Government and Local Finance, Poor Law, National Health Insurance and Contributory Pensions. It is no doubt because the matters to be discussed are so numerous and so diverse that the Chief Medical Officer of the Ministry makes an individual report which appears as a separate volume. In regard to public health, the report shows that the activities in relation to sanitary matters and the health services generally throughout the country were well maintained.

HOUSING, TUBERCULOSIS, ETC.

Water supply was troublesome in certain parts on account of the drought, but by means of increased loans, amounting in all to over three millions sterling, the Ministry sought to help authorities making provision of supplies. A note in regard to the special survey of health services now in progress shows the Minister of Health satisfied with the provision made by the local authorities. Similarly satisfaction is registered following the review of the work done during the year in relation to the working of particular welfare or disease prevention schemes and so on. Provi-

sion for dealing with tuberculosis continues to grow, and very full use is made of the various sanatoria and other institutions provided by local authorities and otherwise. Special mention is made of the work done at Papworth and other village settlements.

In relation to maternity and child welfare also the work of local authorities continues to develop steadily. The infantile mortality rate for the year was 64, the rate of maternal mortality being 4.32 (1.75 for deaths from puerperal sepsis, and 2.57 for deaths from other causes). The total rate in 1932 was 4.04, and in 1931, 3.94. In relation to housing, slum clearance and the provision of new houses are shown to be progressing actively. Exclusive of houses built for re-housing purposes in connection with slum clearance, over half a million were built in 1933-1934. The total annual contribution from public funds to housing is shown to be about 16½ millions sterling.

NATIONAL HEALTH INSURANCE

Poor law and national health insurance work received close attention during the year. In 1933-1934 the average numbers of persons in receipt of institutional and domiciliary poor relief were respectively 185,457 and 1,139,546, a total of 1,325,003, representing 330 per 10,000 of the population. For assistance to distressed areas throughout the country, a special grant of ½ million pounds was voted by Parliament. As indicating the extent of the insurance medical services in England alone in 1933, it is noted that 15,500 doctors were in insurance practice; that medicines, etc., were supplied as part of medical benefit at about 10,200 chemists' shops, and that the number of insured persons entitled to medical benefit was approximately 15,150,000. The cost of medical benefit was just under 8½ millions sterling, of which over 6 millions went to pay insurance

doctors for their services — services which, though it is not in terms stated in the report were greatly appreciated, were of the greatest advantage to the great part of the insured population, and resulted in many cases in securing medical assistance that, in the absence of the scheme, would have lacked it. In his own report (*On the State of the Public Health*), Sir George Newman devotes a section to the insurance medical service, and though he makes no sounding claims as to its excellence, stresses the fact that complaints against doctors are year by year very few; numbering in 1933 no more than 203.

EFFECTS OF UNEMPLOYMENT

In other sections Sir George discusses the situation in relation to such matters as epidemiology generally, tuberculosis, maternity and child welfare, cancer, and so on. Sociological questions also, as usual, receive a great deal of attention, and as he was almost compelled to do so he has much to say on unemployment and the economic depression and their effect on the health of the nation generally. Always his view has been that, in spite of the adverse conditions in regard to employment, the state of the public health and nutrition cannot be shown to have been affected in any degree. This opinion he reiterates and backs with statistics and the evidence of medical officers of health and others in particular areas. In his report as Chief Medical Officer of the Board of Education (*The Health of the School Child*), he refers again, as follows, to the subject:

The indisputable evidence of the national morbidity and mortality rates, of the health insurance returns, and of the school medical

service for 1933 indicates quite definitely that the general health and nutrition of the population of England and Wales, taken as a whole, was well maintained in 1933, in spite of economic and social difficulties, distressing as these have been. . . . There can be no question that the nutrition of the English people is better today than at any past period of which we have record. . . . From the returns of the local education authorities for 1933 it is evident that whilst some schools find undernourishment is present, and has even increased in certain areas or particular groups of school children, it is not generally more prevalent than in recent years, in spite of the economic depression and the mental distress and hardship following in its train. This circumstance is due to the increased care and devotion of the mothers and teachers, to manifold forms of voluntary service, and to the public provision of insurance benefit, school feeding and medical supervision.

Sir George Newman's reports are always scholarly and readable. He writes with conviction, and because it is not always merely as an official setting forth facts and information with regard to which there can be neither question nor dispute, or as a scientist that he writes, but as a humanitarian and a sociologist as well, there is never the feeling that it is with so many figures of people or school children he is dealing, but with living beings who have had a past that may not have been too happy and healthy, and are having a present and will have a future that he is trying to insure shall be better and happier and healthier. In both the school and the general report for 1933 there are many sections in which these things are shown, and I wish very much I might have been able to do more than merely refer to the fact of the existence of the volumes.

CHARLES PORTER, M.D.

London

PUBLIC HEALTH EDUCATION*

Dates Ahead—In March, 1877, a "visiting nurse first started her rounds to sick poor"; St. Patrick, "credited with driving the poisonous reptiles out of Ireland," whose birthday may be applied to the medicine fakirs of today; National Negro Health Week opens in March, 1935.

April Fool's day offers a lead against fakirs and superstitions; the first dispensary opened in April, 1786; National Youth Week closes April in 1935, and leads into Child Health Day.

The above are samples of dates to be used to give timeliness to health publicity. Additional information and dates running throughout 1935 are to be found in "News Almanac for Social Work—1935," edited by Louise Franklin Bache who had charge of health education in the Health Department during the Syracuse Health Demonstration. Of course there are many dates and ideas for nearly all forms of social work, but a goodly proportion may be utilized by health agencies.

Single copies, 50 cents. Address: Community Chests and Councils, 155 East 44th St., New York, N. Y.

Write to Dr. R. C. Brown, U. S. Public Health Service, Washington, D. C., about Negro Health Week; National Youth Week Committee, 211 W. Wacker Drive, Chicago, Ill.; American Child Health Assn., 50 W. 50th St., New York, N. Y., about National Child Health Day.

Testimony from the Advertisers—Last year there were vociferous

applauders of the purity of food and patent medicine advertising and manufacture. But in recent months the full and complete answer could be gleaned from extracts from articles in advertising journals and reports of advertising conventions. When talking among themselves there has been abundant testimony during the fall and winter to the need of legislative control, unless we accept the optimistic view that industry can and will do a thorough cleaning up job.

For information about present and proposed food and drug laws address U. S. Food and Drug Administration, Washington, D. C.

The Red Cross Is Criticised—In *American Mercury*, Nov., 1934, appeared a scathing criticism of the American Red Cross. The extreme insinuations were such as to raise doubts in the mind of a thoughtful reader, but many supposedly factual statements had an appearance of accuracy.

Doubtless the Red Cross, as a very human institution, is imperfect and inefficient here and there. *But the most striking criticisms in the Mercury article are characterized by the Red Cross as gross misstatements of fact or of interpretation.*

A brief criticism, signed by Paul U. Kellogg, appeared in *Survey Monthly* (112 East 19th St., New York, N. Y.), Dec. 15, 1934. A more complete answer is *Red Cross Operations*, a pamphlet issued by the American National Red Cross, Washington, D. C. Copy free.

Because of the public health activities of the Red Cross, public health

* Please address questions, samples of printed matter, criticism of anything which appears herein, etc., to Evert G. Routzahn, 130 East 22d St., New York, N. Y.

workers will wish to know the truth about this magazine article.

The Need for Economic Security—Twelve silhouette charts tell the story in "The Need for Economic Security," a publication of the Committee on Economic Security, Washington. "The annual accident toll" and "Illness among persons in families of varying economic status" directly concern our readers, but most of the diagrams have striking implications for those interested in medical services and the economic factors affecting the health of individuals.

Here is material for lantern slides, for bulletin boards, for reproduction in house organs, as illustrations for newspaper stories, for large scale platform illustration, as the basis for staff and outside group discussion. And they illustrate how much statistical material may be made graphic.

Address: Committee on Economic Security, Washington, D. C. Copies free.

Health Education in January Journal—In *American Journal of Public Health*, Jan., 1935, appeared the following in "Reduction of Maternal and Infant Mortality in Rural Districts":

One of the important functions of a health officer, who is determined to lower the maternal and infant mortality rates in a rural area, is to develop active and efficient lay support of his undertakings. His personality and his ability to interest the public in his child health program may determine his success or failure in this field. This matter of organizing groups of influential citizens to further a community program in behalf of mothers and infants should be given more emphasis in our schools of public health in addition to the many technical and scientific subjects the embryo health officer is expected to master. (Followed by discussion of the organization of interested lay groups.)

Under "The Ninth Pan-American Sanitary Conference" it was stated that

In connection with venereal disease educational measures were advocated . . . and especially the necessity for greatly increased popular health education was discussed.

But most important of all was the editorial, "Medical and Scientific English," on page 85. That editorial, we hope, will be re-read by all who see this paragraph.

The editorial could be used in a number of ways to contribute toward better health education.

Why not reprint most of it in every national and state journal and bulletin?

Why not supply mimeographed or printed copies to all staff members who talk or write or handle correspondence, and to all who write for any of our periodicals?

People Do Read—The American Library Association reports a decrease in the reading of fiction, with continued popularity of books on economics, political and social sciences, among others, as well as a steady interest in success books and occupational works. Could we increase the reading of books on health, the human body and its physical environment by making more of the success phase of health? "Fiction Reading Decreases" (*Publishers' Weekly*, 62 West 45th St., New York, N. Y., Jan. 5, 1935), and "Who Reads What—and Why" (*Nation*, 20 Vesey St., New York, N. Y., Jan. 23, 1935) give some of the facts about readers and reading.

A Newspaper Campaign Reduces Accidents—San Francisco reports success in contrast with the Los Angeles testimony of failure (see this department for Jan., 1935, page 93) in crusading against auto accidents.

Editor and Publisher reports the campaign conducted through 1934 by the *San Francisco News*, crediting it with

. . . a fatality decrease in San Francisco of 14.5 per cent over 1933, while California

and the country as a whole registered an increase of 15-plus per cent. Oakland, across San Francisco Bay, the nearest neighboring city, registered an increase of 38 per cent. The Los Angeles auto death rate per 100,000 population was almost twice that of San Francisco.

These definite results have inspired the *San Francisco News* to plan a continuous campaign during 1935 that will be even more effective.

The plan for 1934 called for "at least one story on safety every day." Actually,

. . . the result was an average of from two to three stories a day, besides scores of illustrations, editorials and cartoons during the year.

For some of the details see *Editor and Publisher*, Times Bldg., New York, N. Y. Feb. 2, 1935. 10 cents.

It Never Was Stopped—The December, 1934, issue carried this paragraph:

The *Monthly Bulletin*, Indiana Division of Public Health, Indianapolis, has been revived under the editorship of Thurman B. Rice.

It never has stopped publication. It merely failed to reach this editor for a period of months. This illustrates how easy it is to misstate the facts without a direct check-up.

A Housing Exhibit for Your City—An unusual Housing Exhibit was shown recently at the Museum of Modern Art, New York City. This display, presented in modernistic fashion, deals with the broad aspects of housing. It is available for other communities. Address Lyman Paine, New York City Housing Authority, 10 East 40th St., New York. Early application is desirable to avoid conflicting dates.

Joint Health Education in New York City—The bigness of New York City seems appalling when a community health education effort is being planned. But the Welfare Council, through its

Health Education Section, has undertaken to focus the activities of health agencies upon a series of monthly topics making each educational effort go further through combining forces. No extra funds will be available, as were expended in the diphtheria campaign, and efforts must be avoided which might lead to new demands upon clinics or nursing services.

The 1935 topics will be as follows:

February—Congenital syphilis; *March*—Heart diseases, Diphtheria and communicable diseases; *April*—Early treatment of tuberculosis; *May*—Maternal and child health, Dental and oral hygiene; *June*—Nutrition, Summer care of children; *July*—Safety and accident prevention.

In the Great Smoky Mountains—"Thoughts on Nutrition and Health in the Mountains," after describing conditions says:

The problem of diet in the mountains is partly economic but not wholly so, for we sometimes observe people in good condition so far as economic status is concerned, who do not have proper diet. I feel convinced that the real solution of this health problem is to be found in education. . . . But it will require the coöperative efforts of doctors, public health nurses, vocational agriculture and home economics teachers, county agents, home demonstration agents, and others, for a long time, to carry through this program of education.

By Dr. R. F. Thomas. *Mountain Life and Work*, Berea, Ky. Jan., 1935. 30 cents.

Health Education in India—In the annual report of the Bombay Branch of the Baby and Health Week Assn., Bombay, India, we find a picture of "a stall in the Foods and Vitamins Exhibition arranged at Byramjee Jeejeebhoy Home of the Society for the Protection of Children in Western India, at Matunga." There is described a "scheme of health propaganda" submitted to the Director of Public Health and the Surgeon General, at Poona.

Free cinema shows, lectures with magic lantern slides, and the exhibition of models showing by contrast measures that improve the condition of the villager and those that are lowering it at present are the chief items with which my association has carried on propaganda for the last 8 years with remarkable success. Such demonstrations have necessarily to be followed by some permanent measure for his relief such as the improvement of village water supply, removal of dirt from the village, training of Dais and their supervision, etc. But the Exhibitions and Cinema Shows help the welfare worker a great deal in dispelling superstitions and securing the voluntary coöperation of the villagers.

Preparation for Better Service—

In February a 1-week institute for tuberculosis workers was held by Massachusetts Tuberculosis League in Boston, with Philip P. Jacobs in charge. Prof. C. E. Turner presented adult health education and school health education.

An Institute for Tuberculosis Workers is being held in the first 2 weeks of March, 1935, by National Tuberculosis Assn., and New York University, with Philip P. Jacobs, Ph.D., conductor. Several sessions will be devoted to adult and child health education.

Home Hygiene Instructors' Institutes will be held in a number of states by the American Red Cross. The Home Hygiene Service conducted 26 Institutes in 1932-1933, and 45 in 1933-1934.

"Dental Health Education," by J. M. Wisan, D.D.S. Describes an extension course for teachers and nurses conducted by Newark, N. J., State Normal School. *Child Health Bulletin*, American Child Health Assn., 50 W. 50th St., New York, N. Y. Jan., 1935.

Calgary, Uganda, and India Prize Winners—Annually the National Baby Week Council, London, England, makes a series of awards for the best Baby Week Campaigns held in British Empire outside of Great Britain.

First prize in 1933-1934 went to the

Calgary (Canada) Council on Child and Family Welfare.

Second place went to Kampala, Uganda, for

... an extremely good campaign, which followed very much the same lines as those adopted for such campaigns in this country (England), though it was adapted with great skill to meet the problems presented by a native and often illiterate people. A wonderful baby show was held during the Week, for which 72 African babies and 100 Asiatic babies were entered, and a particularly forceful event in the programme was the Infant Welfare and Public Health Exhibition, which attracted more than 75,000 people.

The third award went to Mysore, India, with additional awards to points in India, Ceylon and Africa.

For additional information see *Mother and Child*, 5, Tavistock Square, London, W.C.1. Sept., 1934. 9d.

Hygeia for February, 1935—Material for speakers and writers and for reference, in *Hygeia*, 535 N. Dearborn St., Chicago, Ill. (free copy to health workers):

New food and drugs legislation. Undulant fever—then and now (with good picture diagram on pasteurization). A heart-to-heart talk about hearts (a radio talk). Preventable diseases in the Washington family (history for popularization). The challenge of the slums (new housing possibilities). Science and health and the key to the crime wave (cartoon by Ding). Experimentation and medicine: man's debt to the animal world. Occupational diseases of musicians (more of them). "Occupational diseases" of children (a second lot). Health education in Arizona (a project already 7,000 miles long). The clothes moth (the 9th parasite). The golden age of prevention (about teeth). The eyes in infancy and childhood. Exploding a sinus fallacy. Old Boston school days (more usable history). The A.M.A. and tomato juice. New books on health. Questions.

For teachers and others: Healthy children—the teachers goal. The report card comes home (mental hygiene). Enjoying trips to the dentist (a story of genuine achievement). Fruit goes up a point (in a high school lunch room). New health books for teachers and pupils.

A.M.A. radio programs, too late for listing

here, but announced for NBC network on Tuesday at 5 p.m., E.S.T., and Columbia network, Thursday at 4:30 p.m., C.S.T.

Learning on the Job—A number of round tables have been offered by the New York Social Work Publicity Council for these groups:

Those who wish to learn about methods and materials

Those who have specific questions or special needs

Those who wish to think out and talk over technic or principles and philosophies

Wherever two or more health workers may get together to talk over such topics as are offered in New York, it is likely that health education will benefit. Also, there is a widening of experience and information where the health workers may join with workers in other social welfare fields.

One of the simplest and most effective means for learning on the job is to talk over and think out with others the basic technics.

The Social Work Publicity Council will be glad to share ideas and outlines with anyone who will get together with at least one other person to discuss any of the topics which follow.

Amateur movies: What practicable values do amateur movies offer to social agencies in or near New York City? how inexpensive they are? how to get them?

Annual reports: The uses of annual reports and how to fit them to those uses.

Broadcasting: The philosophy of health and welfare broadcasting, and its practical application, including the critical examination of proposed plans and materials.

Health education for adults: An exploratory group: What is health education? What are the particular problems in conducting effective health education in New York City?

Making ideas and statistics graphic: On making reports, plans, statistics, etc., interesting and clear to board members, committee meetings, general audiences, and in publications.

Meetings: The reduction of meeting or conference overhead of social worker groups; the improvement of quality and value. If this year you will arrange or lead or speak at

or attend even a single meeting, small or large, this group will serve you.

Mimeograph and other duplicating processes: About more and better use of duplicated material, and better duplication.

Newspaper releases: *Limited* to those who will submit releases for friendly comment and constructive criticism by the group and the guest clinician.

Photography in social work: How we may get better service from professional photographers; where the amateur may serve; new types of photographs "instead of the same old stuff."

Printed matter clinic: Samples of printed matter or of copy for printed matter will be submitted for friendly criticism by the group and by invited clinicians. *Limited* to those who will submit samples for review.

Statistical data for publicity use: Kinds of data having publicity value; what annual or quarterly statistics can be used to advantage; what general or governmental data may be of value; collecting data primarily for publicity; channels for use.

Volunteers in publicity: To explore the practical possibilities in publicity service of various types by volunteers. Open to volunteers, executives, publicity workers.

Window displays and other exhibits: Planning and preparation of window displays and other exhibits; to include consultation sessions with a display man, photographer, etc.

For copy of the full list with other details send 3 cents postage to Social Work Publicity Council, 130 East 22d St., New York, N. Y.

Wanted for Awards—Descriptions of successful projects in health education will be considered by the Awards Committee of the Social Work Publicity Council, 130 E. 22d St., New York, N. Y., in making selections for the annual citations for merit. These must be received before April 1.

Wanted for Milwaukee—What ideas have you for development at Health Education and Publicity Headquarters? What display could you set up? What display idea would you illustrate?

Early collaboration will add interest and value to the center at the A.P.H.A. meeting for those concerned with health education.

Wanted for the JOURNAL—We are sure that much good and useful health education material issued by local, state, and national health agencies does not reach this department of the JOURNAL.

Will the health officer or the association executive or the supervisor of health education, or whoever is in authority, please designate some member of the staff to be responsible for sending copies of material already issued in 1934–1935, also new material issued during the remainder of 1935?

Wanted by the Editor—Have you prepared an amateur movie on health education? Have you used marionettes or puppets?

EXHIBITS

The Southern Medical Association gave an award to Texas Dept. of Health for its exhibit of Texas malaria control. The exhibit was almost wholly of well labeled objects.

"A Hospital Stages Its Own Historical Exhibit" describes an exhibit put on by St. Peter's Hospital, New Brunswick, N. J. Hospitals will wish to look up the details in *Trained Nurse*, 468 4th Ave., New York, N. Y. Feb., 1934. 35 cents.

Baltimore Health Dept. recently exhibited The Big Bad Wolf—Diphtheria.—illustrated in *Baltimore Health News*, Oct., 1934,

"We built our house of straw" (house down and out): "No Toxoid Prevention—Thought it was just a sore throat—and didn't call a doctor—*Diphtheria*."

"We built our house of sticks" (and showed it): "No Toxoid Prevention—Called the doctor too late—*Diphtheria*."

"We did not dare take a chance. We built our house of bricks" (and it shows): "Toxoid Prevention—Given each child 6 months of age."

The Health Service of Howard University, Washington, D.C., conducted an exhibit on cancer. Among more conventional features were the following as reported by Dr. E. H. Allen:

Our Art Department painted a large caption "This individual is on his way to the physician to get intelligent information concerning cancer." I constructed in a cut-out below this caption a Mickey Mouse on a cardboard back in the act of hurrying somewhere in business-like manner. It was my original idea to use a jumping jack for the purpose of portraying continual motion, but I was unable to secure one at the time. A note of levity was hereby included which I think to be of some value. I also used the suggestion of a mirror with an attractive caption "This individual should have intelligent information concerning cancer." It worked.

Wisconsin Anti-Tuberculosis Association had a traveling exhibit as a feature of its Silver Jubilee. More than 44,000 saw the exhibit in 11 cities. The story is told of how 5 members of 2 families were placed in a sanatorium because 2 children from different families visited the exhibit in one city. The exhibit was

. . . a revival; a Spring Health Festival in which the truth about how to live to prevent and cure tuberculosis was brought freshly to some and reiterated to others.

The Dept. of Health Education for Boys of Seward Park High School, New York City, conducted a health exhibit as a teaching project:

The exhibits selected were practical. They applied to the everyday life of the adolescent, and were somewhat different from that generally presented as part of the course in hygiene.

The material was arranged to appeal to seasonal interests and to stimulate curiosity in games, skills, and practices partly or wholly unknown to the pupils before this exhibit.

Among the units displayed were: Sunburn, Posture, Poison Ivy, Care of feet, Poisonous toadstools and edible mushrooms, Hornets, Snakes, Dental exhibit, First aid and resuscitation, Camping, Milk and nutrition, Medical examination, Safety.

REPORTING

"When a Community Desires Health," a good line, is the title of

Detroit's Department of Health report for 1933.

The Township Board of Health, Maplewood, N. J., has used the mimeograph quite successfully in producing a 10 page report, 5½" by 8½".

Again the New York City Department of Health reported Jan. 1, 1935, on the city's health record in the year before, including numerous comparative tables of death rates for 5 years. 13 legal size mimeographed sheets.

The original health exhibit street car; the "Health Gypsy" who last year visited 315 schools and other groups; "Gypsy Gay" and "Professor Health," radio health talkers, are the more unconventional features mentioned in "Thirty Years of Tuberculosis Work in St. Louis." This reports on Tuberculosis and Health Society, 613 Locust St., St. Louis, Mo.

"Their Health Is Your Health" (quotation from Alfred E. Smith) is the title of a money raising report of Henry Street Visiting Nurse Service. Including self-cover, 16 pages; lower case side heads in blue; both illustrations and statistics presented in Neurath symbol pictures done by Pictorial Statistics, Inc., simple pictorial district map on the cover. The whole effect to be seen to be appreciated. 99 Park Ave., New York, N. Y.

TO DO OR NOT TO DO

Is not 10 better than ten, or 1,000 better than one thousand, when we are writing copy and really wish the mind as well as the eye to recognize our important facts?

"Lantern Slides," by S. Schaffer. *Safety Education*, 1 Park Ave., New York, N. Y. Dec., 1934. 20 cents. Describes several methods for producing slides—on other subjects as well as safety.

Something for health workers to be on the watch for is reported in *Bulletin of American Hospital Assn.*:

The Anti-Vivisectionists, with ample funds at their disposal and with the support of powerful newspapers, are conducting an energetic campaign in 32 states, and are organized, as they publicly announce, to carry their fight to the finish. Model bills against vivisection will be introduced in 32 state legislatures at the coming sessions.

The enactment of these laws would be highly inimical to medical research. It would impede medical progress and hamper medical education. To prohibit animal experimentation would destroy the processes that have yielded many discoveries that have contributed to the prolonging and saving of the lives of many millions of our fellow-beings, particularly of our children.

Several articles have been written for those who are interested in the educational possibilities of the picture symbol as devised by Dr. Neurath. "The Neurath Pictorial Statistics," by M. E. Schwarzman, is accompanied by illustrations, and several reading references. *Progressive Education*, Washington, D.C. March, 1934. 50 cents. "Statistics for All," same author. *Educational Screen*, Chicago, Ill. Sept., 1933. 25 cents.

The seventh Gorgas Essay Contest is announced by Gorgas Memorial Institute, 1835 Eye St., N.W., Washington, D.C. Open to high school students; closes Feb. 15, 1935; with local, state, and national prizes. The committee seems to blunt the contest as an educational tool by offering a group of topics for the essay writers, rather than to seek widespread concentration on a single idea:

The conquest of yellow fever in Havana. Gorgas' work in Panama as a factor in building the Panama Canal. Gorgas as Surgeon General during the World War. The bearing of Gorgas' work on the health problems of today. Importance of the Periodic Health Examination during the World War and as a health measure today. Insect-borne diseases and present status of their control.

SCHOOL HEALTH EDUCATION

"Health Education in a Rural County," by R. E. Grout. Especially the part of school nurses in Cattaraugus

County. *Public Health Nursing*, 50 W. 50th St., New York, N. Y. Sept., 1934. 35 cents.

"Health Education in the State Normal School at Towson, Md.," by Spencer and Dowell. A school health monograph. Includes extensive reading references, without mention of prices. Metropolitan Life Insurance Co., New York, N. Y. *Free*.

"A Project in Rural School Health Education: Relationship with Community Health Programs," by Ruth E. Grout. *Quarterly*, Milbank Memorial Fund, 40 Wall St., New York, N. Y. Jan., 1935. Fourth in a series by director of health education study in Cattaraugus County.

"Health Education: The Review Lesson," by H. L. Conrad. Eighth in a series. *Mind and Body*, New Ulm, Minn. Dec.-Jan., 1935. 25 cents.

A "School Health Guide" comes from County Health Officer, El Centro, Calif. Mimeographed; 31 letter size pages. Health service; health education; health information.

MAGAZINE ARTICLES

"A New Deal in Dietetics," by Mary P. Huddleston, editor of *Journal of American Dietetic Assn.*, in *New York Herald-Tribune Magazine*. Dec. 9, 1934.

Today's nutrition points the way to buoyant youth, high adult vitality and longer life. A diet already adequate can probably be enhanced by added amounts of protective foods to insure positive and glowing health as well as protection against disease. . . . We may well believe that the dietary millenium has dawned. . . . Irradiated foods in general seem to be the latest word in dietetics.

"Saints, Witches and Babies," by Louise Summers. Health conditions among Mexicans in Arizona; "but a little understanding of the Mexican temperament and the Mexican background (and it is in this article) would at least throw some light onto the

subject." *Junior League Magazine*, 305 Park Ave., New York, N. Y. Feb., 1935. 30 cents.

FOR USE OR REFERENCE

"Good Posture in the Little Child," a poster based upon the pamphlet of same title. U. S. Children's Bureau, Washington, D. C. Both are *free*.

Historical material on diet and eating habits in "Vegetables in the Diet: Yesterday," by S. L. Smith (To be followed by "Today" and "Tomorrow.") *Journal of Home Economics*, 101 East 20th St., Baltimore, Md., 30 cents. Later the series will be reprinted for 15 cents.

In her syndicated column, released Dec. 16, 1934, Mrs. Roosevelt expressed an appreciation of the U. S. Public Health Service and told something about its history and present activities.

"Introducing Mr. Public Health," *Iowa Public Health Bulletin*, State Dept. of Health, Des Moines. Oct.-Dec., 1934. A public health study outline in 6 lessons intended for members of Congress of Parents and Teachers, Women's Division of Farm Bureau Federation, Federated Women's Clubs, etc. Covers the field but fails to focus attention upon adult health education.

A new set of 5 posters, "Healthy Childhood," has been issued by National Council for Maternity and Child Welfare, 117, Piccadilly, London, W. I. The text is limited to three or four words, such as:

Rest and sleep; The right food; Nature's food is best.

"Our Attitude Towards Cancer 'Cures,'" *Bulletin*, American Society for Control of Cancer, 1250 6th Ave., New York, N. Y. Jan., 1935. 10 cents. Why "cures" are tolerated; need for testing station.

Public Health Reviews, is an 8 page monthly issued by Division of Hygiene and Public Health, University of Michigan, Ann Arbor. Includes summaries

of current books, selected articles and pamphlets. *Free.*

"The Social Adjustment of the Tuberculous," by B. W. Burhoe. National Tuberculosis Assn., 50 W. 50th St., New York, N. Y. *50 cents.*

"Social Hygiene and Family Case Work," is a set of charts "of special interest to nurses, medical social workers, and others interested in family health and welfare." How syphilis spreads, case finding, pregnancy, etc. Miniature sets, letter size, *10 cents* (quantity rates); 17×22 inches, \$1.00; colored and mounted, \$5.00. American Social Hygiene Assn., 50 W. 50th St., New York, N. Y.

"That Mean Cold" is an old title but a brand new booklet. Simple cuts, small pages, a sub-title on nearly every page, well leaded type—all contributing

to easy reading. 11 pages and cover. John Hancock Mutual Life Insurance Co., Boston, Mass. *Free.*

That "Measles Threatens" we are reminded under that title which brings out the measles cycle as shown by New York morbidity statistics. *American Journal of Nursing*, 50 W. 50th St., New York, N. Y. Feb., 1935. *35 cents.*

"When the Unexpected Happens" is a first aid manual. A very clear table of contents; black face side heads; additional sub-headings centered on pages; simple illustrations with descriptive captions. One wishes that a little larger type could have been used to make easier reading when the user is excited by an emergency. 30 pages. John Hancock Mutual Life Insurance Co., Boston, Mass. *Free.*

BOOKS AND REPORTS

Amebiasis and Amebic Dysentery—

By Charles F. Craig, M.D. *Springfield, Ill.: Thomas, 1934.* 315 pp. 54 ill. Price, \$5.00.

The epidemic of amebic dysentery in Chicago in 1933 emphasized the deplorable lack of knowledge of amebiasis and amebic dysentery by the medical profession and laboratory workers in this country, and created an insistent demand for an authoritative treatise which would be of practical value as a reference book. This demand has been met in an exceptional manner by Colonel Craig who is considered the best authority on the subject in this country. The monograph which he presents will undoubtedly stand as a classic in medical literature and will find immediate use in all medical libraries as well as in the hands of many physicians, public health workers, and laboratory technicians.

The monograph contains 12 chapters. The first deals with the history and geographical distribution of amebic infection and emphasizes the fact that acute amebic dysentery is only one of the many manifestations of infection with *Endameba histolytica*, and that the parasite is of world-wide distribution and an important cause of disease in temperate as well as in tropical regions. The chapter on etiology describes *E. histolytica* in detail, its life cycle, and its method of reproduction and transmission. It is illustrated by excellent photomicrographs and drawings.

The chapter on epidemiology takes up the subject of incidence, sources of infection, variations in the effect of the ameba on different individuals, epidemics, reservoir and transmitting hosts,

and the influence of age, sex, race, climate, and individual immunity to the disease.

The two chapters on pathology describe in detail the gross and microscopic lesions produced in the intestines and in other organs and tissues of the body. They are illustrated by splendid photographs, mostly from the U. S. Army Medical Museum. Symptomatology, complications and sequelae are treated in great detail. The clinical manifestations of amebic infection and the wide variation in the symptoms and physical signs which may be produced are emphasized.

The chapter on clinical diagnosis calls attention to the difficulty of differentiating amebic infection as it affects the intestine, liver, lungs, and other organs from other diseases. The chapter on laboratory diagnosis describes in detail the other amebae which are found in the human intestine and emphasizes the importance of well trained technicians in their differentiation. It also describes methods of fecal examination and the technic of artificial cultivation of *E. histolytica*.

A chapter is devoted to a consideration of the complement fixation test, which was originated by the author and has proved to be of value in diagnosing obscure cases of amebiasis and in following the effects of treatment.

The discussion of prophylaxis is of special interest and value to public health workers. It stresses the importance of proper disposal and treatment of human excreta, the protection and sterilization of water supplies, the necessity for careful supervision by health officials of the plumbing in public buildings, the protection of food from

flies, and the supervision of public food handlers. Emphasis is laid upon the importance of personal sanitation and educational measures to prevent the spread of amebic infection.

The final chapter on treatment is especially valuable. The author discusses the history and use of all the drugs which have been advocated in treatment. He warns against the excessive use of emetine and other drugs of high toxicity and calls attention to the newer drugs which have been found to be more effective and less toxic. He outlines the treatment for amebic infections of varying degrees of severity as well as the medical and surgical treatment of amebic abscesses of the liver and lung. This chapter should prove to be of special value in encouraging safer and more effective treatment of infected individuals. Each chapter is followed by an extensive list of references and the book is furnished with a complete index.

The book is beautifully printed and well bound, for which the publisher is to be congratulated. The reviewer recommends it most highly to all public health workers. HENRY E. MELENEY

Recent Advances in Allergy—

Asthma, Hay Fever, Eczema, Migrant, etc.—By George W. Bray. Philadelphia: Blakiston, 1934. 503 pp. Price, \$5.00.

The second edition of Bray's book represents the most comprehensive review on this subject which has appeared. It is written in even better and more readable style than his first review, published some 3 years ago.

Bray's broad personal experience with the study of allergy has enabled him to read and write on the subject in an understanding way. He illustrates his own subject matter by citing and reviewing an enormous number of articles in logical order and sequence. He takes up practically every phase of

the subject and discusses it adequately and well, and in a style which, though brief and concrete, is blessed with clearness.

The book shows throughout that the enormous volume of literature which we have on allergy can be mastered by the industry and intelligence of one man, and that it can be presented in such a way as to be used by students and writers on almost any branch of the subject for obtaining a brief and clear review of late literature in a short period of time.

This stupendous effort on the part of Bray ought to be appreciated and used by students and writers on allergy who wish to acquaint themselves quickly with the recent ideas on this subject without the necessity of reading the hundreds of articles which have been written on each different phase of the subject.

I wish to acknowledge with thanks, Bray's acceptance of physical allergy (altered reactivity to the action of physical agents) as a specific clinical entity which can be, though need not necessarily be, related to sensitiveness caused by material agents.

The book can be recommended as one of the most complete and beautifully written reviews which has appeared on the subject. The printing and make-up of the book are excellent.

W. W. DUKE

Poliomyelitis. A Handbook for Physicians and Medical Students—By John F. Landon, M.D., and Lawrence W. Smith, M.D., with a section on Orthopedic Aftercare by Gary DeN. Hough, Jr., M.D. New York: Macmillan, 1934. 275 pp. Price, \$3.00.

This small volume summarizes the knowledge and handling of poliomyelitis in the hospital which bore the brunt of the two largest epidemics of this disease in history. It can be recommended as

a well considered, sane, and competent handbook, without bias toward particular theories or procedures, and balanced in its consideration of the various aspects of the disease. The important section on aftercare has naturally been entrusted to one familiar with the results rather than with the acute stage of the disease. It is interesting that in contradiction to a recent German book on the disease which devotes only a short paragraph to reëducation, the procedure which, combined with rest or avoidance of stretching the weakened muscles, is fundamental in the treatment of poliomyelitis, the present volume stresses these principles as laid down by Dr. Robert W. Lovett.

In regard to the much debated use of serum for treatment or for prophylaxis, the weight of the authors' opinion seems to be against serum being of any benefit in treatment, and as for prophylaxis, the most that is said is that "it gives great psychological satisfaction to anxious parents." J. P. LEAKE

The Doctor in History—*By Howard W. Haggard. New Haven: Yale University Press, 1934. 408 pp. Price, \$3.75.*

This book, according to the author, is an attempt at a "history of health," written allegedly for his children. As such, there is no attempt at scholarly treatment, and the work gives the impression of a series of sketches. The style makes it easy to read, and the book is entertaining, though it contains little that a man who is moderately well informed does not know, except for an interesting detail here and there.

The picture of the "doctor" throughout history until quite recent times gives the lay reader the vivid impression of a being with whom it would be very dangerous to visit even if in good health, and especially so if ill. This being originally crystallized the superstitions of primitive man to his

personal advantage, and later lagged behind the march of general human progress by several centuries, not to be budged from Galenic tradition either by the evangelism of Paracelsus or the satire of Molière. Perhaps this is a true picture.

The book is profusely illustrated with interesting woodcut reproductions, some of which have a bearing on the text. Many have no apparent bearing, as for example, one on page 162, showing certain forms of legal torture. It is nowhere explicitly stated whether this was one of the functions of the medical profession or not.

The volume is well indexed, though for what purpose, it is difficult to say.

ALLEN E. STEARN

A Nutrition Program and Teaching Outline—*Prepared and published by the Philadelphia Child Health Society, 311 South Juniper Street, Philadelphia, 1934. 156 pp. Price, \$1.00 postpaid.*

This volume is a complete revision of the first edition of 1927, bringing up to date the factual material and educational methods. It has been developed primarily for use in the health centers and clinics of the Division of Child Hygiene, Department of Public Health of Philadelphia; but it may be adapted readily to similar centers in other parts of the country.

As stated in the foreword of this outline,

This outline continues the clarification of the laboratory findings, elaborates on the special value in certain foods and combinations of food, and stresses proper methods for the preparation of foods. It also stresses the value of good health habits, inculcated early as an important adjunct to nutrition; it brings to the attention of the student or reader the important part played by the removal of physical defects which so frequently interfere with proper nutrition even when the best balanced diets have been supplied.

Nutrition and diets for children at various age levels are given as lesson outlines which may be used flexibly in health centers or in mothers' clubs and classes. The outlines are presented clearly and concisely with helpful illustrative material and references. A selected list of reference from recent literature on nutrition appears at the end of the book. RICHARD A. BOLT

Practical Everyday Chemistry—By H. Bennett. New York: Chemical Publishing Co., 1934. 305 pp. Price, \$2.00.

This book should prove to be a valuable manual in many laboratories as it gives directions for preparing a variety of products as well as the composition of many common products. Various chapters give working formulae for adhesives, agricultural products, paints and related products, cosmetics and drugs, food products, beverages, inks and carbon paper, leathers, oils, constructing materials, paper, photography, plating, polishes, rubber and plastics, soaps and cleaners, textiles and many other products in use in daily life. One chapter includes tables, and other useful information regarding sources of information and materials.

Brief introductory paragraphs at the beginning of each chapter are informative. In some cases, these could have been enlarged to advantage. The author has had previous experience as the Editor of the *Chemical Formulary*.

C. S. PEDERSON

Your Meals and Your Money—By Gove Hambidge. New York: McGraw Hill, 1934. 190 pp. Price, \$1.50.

As a basis for a popular presentation of sensible diets in relation to income, Mr. Hambidge has taken the data compiled by the nutritional workers of the U. S. Department of Agriculture. These he has expanded into a readable and

authoritative text, written with a sparkle, which transcends in interest and entertainment the scientific material usually emanating from government bureaus. The average consumer faced with the problem of securing real nutriment from a restricted food budget will get many practical suggestions from the author's series of plans for diets at various levels of nutritive content and cost. Although writing primarily for the lay consumer, the author, hitherto a stranger to the complex field of dietetics, has wisely gone to the leading nutritional authorities for material and has shunned the false precepts of the food faddists who are so ubiquitous and so vociferous in this country. Health officials and physicians will find the book well worthwhile, and relief workers will find it indispensable. The average taker of sustenance may be jogged out of a rut by it.

JAMES A. TOBEY

The Theory of Play—By Elmer D. Mitchell and Bernard S. Mason. New York: Barnes, 1934. 547 pp. Price, \$2.80.

The changes that have come during the last decade in our knowledge of psychology and in the technics in the field of recreation and physical education have made necessary the rewriting of the material in this book, which appeared in 1923 as *The Theory of Organized Play*, by Wilbur P. Bowen and Elmer D. Mitchell. The result is an excellent text.

It is divided into 4 major parts: Historical Background; Theory of Play; The Need for Play; and Administration of Play.

In their discussion of the theories of play, the authors expound as the most likely one the theory of play as self-expression. We play as we do because of our physiological and anatomical structure, our physical fitness, and our psychological inclinations. The type of

play, too, is influenced by habits and attitudes (training), by social contact and physical environment. Certain "universal wishes," such as those for new experiences, for security, for response, and for recognition, also impel us to play. To these may be added the wish for participation and the wish for the esthetic or beautiful.

For public health officials and agencies this discussion of the philosophy of play should have deep interest, since the success of health campaigns depends so intimately on health education.

This text is our most thorough, dependable, and interestingly written treatise on the theory and administration of play. It should be a part of the library of every educator.

CHARLES H. KEENE

A Short History of Some Common Diseases—*By divers authors. Edited by W. R. Bett. London: Oxford University Press, 1934. 211 pp. Price, \$3.50.*

The editor describes this book as an original venture in medical literature. So it is. It is for the most part interesting and well written, and if it is followed by another volume giving the history of a larger number of diseases, it will have a distinct place in the history of medicine.

It has not been as carefully edited as it might have been. It grates on one, for example, to find the isolation of insulin ascribed to Macleod, Banting, and Best. The fact is that laboratory facilities had been given to Banting and Best during the summer when Macleod was in Europe, and that he had rather discouraged Banting. When Macleod came back and found that the epoch-making discovery had been made, he organized further research and assisted in the production of insulin, but the discovery belongs to Banting, who was assisted materially by Best.

There are also mistakes in spelling

of proper names, which is generally considered inexcusable. The name of J. F. Schamberg is spelled with an "o."

The book is well printed and of convenient size. MAZYCK P. RAVENEL

Nursing Schools—Today and Tomorrow—*Final Report on the Grading of Nursings Schools—New York City, 1934. 268 pp. Price, \$2.00.*

What is wrong with nursing? What should we expect of the professional nurse? Why are there so many unemployed nurses and still so many sick unnursed and so many hospitals understaffed? This final report of the Committee on the Grading of Nursing Schools answers these and many other questions, giving us cold facts gathered in their 8 year studies carried on all over the United States. For the nursing schools it suggests a course ahead in which nursing education may be conducted on the same educational basis as that of all other professions. For the private duty nurse it offers hope for practical plans of providing quality nursing to patients who need it at a price satisfactory to both the nurse and the nursed. For the administrators of hospitals and nursing schools it gives not only definite and to-the-point plans for providing nursing service without dependence upon student service, but can also point to successful completion of such plans in different parts of the country. For the consumer, the public, the book represents a sincere effort on the part of a profession engaged in a vital community service to find a way in which it can best meet the needs of that consuming public, if the public will but hold up the hands of the profession.

The picture that this final report gives of the present status of nursing schools in this country does not engender pride in our hearts. However, the improvement made in the 8 years since the committee made its first grad-

ing, and the brave stand which the committee has taken regarding the way ahead promise a hopeful future.

Public health workers interested in the supply of public health nurses, the greatest agents for carrying health teaching into the home, cannot afford to ignore the pertinent facts in this book

VIRGINIA A. JONES

The Child: His Origin, Development and Care—*By Florence Brown Sherbon, A.M., M.D. New York: McGraw-Hill, 1934. 707 pp. Price, \$3.50.*

This is no ordinary book on child care. It bears the marks of careful and prolonged scientific scholarship and covers thoroughly the whole range of child life as an integrated pattern of the social structure. The only book comparable to it in English is Feldman's *Principles of Ante-Natal and Post-Natal Child Hygiene*, published in 1927.

Dr. Sherbon, however, is not content with merely stating the results of modern biochemical and physiological research; she relates these definitely to a philosophy of child life which runs consistently through the entire volume. If one were to attempt to capture this philosophy, it might be stated to be the Gestalt psychology of structural patterns framed in the theory of relativity. She writes that

When we try to put these two ideas together—relativity and pattern—they integrate very consistently. Life ever struggles toward patterned form and expression, a struggle into which the factors of relativity to environment and time ever enter.

Reviewing the factual material in this fascinating volume, I find an arrangement which is logical and which covers the entire gamut of the child from ovum, and before, to his entrance into school. The chapters are grouped conveniently into three parts:

I. *Before the Child*: Fundamental

organization of life; physical and social heredity; anatomy and physiology of reproduction; love, courtship and marriage; physiology and hygiene of pregnancy.

II. *Enter the Child*: Factors relating to birth and puerperium, the baby's first year, the important principles of the hygiene of infancy and childhood.

III. *Development, Behavior and Training*: Section which brings up to date the growth and development of the child, including the new theory of behavior and learning and describing carefully the various developmental periods as they shade into one another. Two helpful chapters for students and parents are "Religious, Aesthetic, and Moral Training of the Young Child" and "Observation of Young Children."

The book is illustrated beautifully and appropriately, especially the chapters on growth and development of the child. A selected list of references is found at the end of each chapter. The glossary of more technical terms and the complete index will prove very helpful to the student. This is a book which every student of the child should read from cover to cover, thoroughly digest, and then keep close at hand for ready reference. RICHARD A. BOLT

Periodic Fertility and Sterility in Woman: A Natural Method of Birth Control—*By Professor Hermann Knaus, Head of the Clinic for Gynecology and Obstetrics of the German University of Prague, with a Foreword by F. H. A. Marshall, F.R.S., translated by D. H. and Kathleen Kilchin. Vienna: W. Maudrich, 1934 (Concip Co., Hobart, Indiana). 162 pp. 64 ill. Price, \$6.50, including a separate special calendar in pocket. Calendar alone \$1.50.*

Studies of this kind are of great value, not so much because they provide an assured hope of a safe period,

so expanded that it will include all but 1 week out of each month, as because they will beget a powerful impulse toward regular recording of dates of menstruation and fruitful and unfruitful intercourse (and also of midmonth discomfort pointing to ovulation), and thus secure sorely needed factual material. As long as observations on human beings lack accuracy inherent in biology in cages, we have to depend on assessment of the truth of claims like those of Ogino and Knaus by checking against each other long series of patients' histories from various sources. At present the only real test of the Ogino-Knaus assurances is at the possible cost of one more child, or one more abortion.

The form of calendar is a device worth while for the intelligent, or doctor-guided, in that it demonstrates at a glance regularity or irregularity in the person keeping it, and the average length of her cycle. Several important studies show that, among women, less than 60 per cent have a 4 week type, even when admitting a range of 4 or 5 days. Thus accumulating evidence on the frequency of irregularity rather vitiates the utility of some of the new formulae. As a prime necessity and preliminary for using the calendar, Knaus insists that it must be kept for a year "scrupulously and without fail," in order that thereafter his conclusion can be put to work, namely, the "unimpeachable certainty" that "in women with normal physiology, *ovulation always takes place on the 15th day before the onset of the period.*" Always? On a given day?

Ogino, as Knaus shows, had preceded him in insistence on counting backward, but Knaus based his conclusions on new experiments, devising a way of registering uterine contractions to show that after corpus luteum formation, pituitary extract no longer caused contraction of the uterine muscle layers, either in rab-

bit or woman, thus demonstrating dates of ovulation.

The book presents an excellent and lucid review of the whole subject and a comprehensive bibliography. Now we await the evidence of extensive and well attested experience from those who seek the most fertile days as well as those who plan to avoid them. And we hope for new research to discover tests of irregular habits of ovulation—tests that are readily available, these, in turn, being predicated on funds for developing them.

Recent publications for professional and lay readers include the following:

Miller, A. G., Schulz, C. H., Anderson, D. W., Miller Clinic, Hobart, Indiana. *The Conception Period in Normal Adult Women.* *Surg. Gynec. Obst.*, 56: 1020-1025, 1933.

Miller, A. G. Is the "Safe Period" Safe? *Biol. and Med. Aspects of Contraception.* Edited by Margaret Sanger. Nat. Com. on Fed. Legislation for Birth Control. Washington, 1934, pp. 28-37.

Ogino, K. *Conception Period of Women.* Med. Arts Publishing Company, Harrisburg, Pa., 1934.

Pederson, Victor C. *Nature's Way.* Putnam, New York, 1934.

HAVEN EMERSON

Keeping a Sound Mind—By John J. B. Morgan. New York: Macmillan, 1934. 440 pp. Price, \$2.00.

In these days of increasing appreciation of the importance of mental hygiene, this book should be a valuable find for persons seeking a really good textbook in that field, prepared with the college student in mind. The material is based upon modern psychology, but so stripped of technical terminology that the layman or the college freshman can comprehend it fully. Such intriguing chapter headings as *How to Fight*, *How to Get Things Done*, *Getting Along with People*, arouse a curiosity to sample those particularly suggestive chapters.

With its excellent table of contents, logically progressive chapters, review questions at the end of each chapter, a brief list of references for further reading, and its complete index, the book meets such requirements in text-

book construction. The author presents material the use of which would aid the student in the establishing of desirable mental and emotional habits, and the acquiring of the right attitudes toward the game of life.

The book is well printed and bound.

ELSIE B. SNEED

Leisure-Time Interests and Activities of Business Girls—By Janet Fowler Nelson. New York: The Woman's Press, 1934. 113 pp. Price, \$.75.

This Research Study was conducted during 1931–1933 under the Laboratory Division of the National Board of the Y.W.C.A. by the Director. Necessarily, in so brief a report, it is largely statistical.

These young business women make up an increasing proportion—16.6 per cent in 1920, 18.8 per cent (2,000,000) in 1930—of employed women. It is a factual study of 1,000 young women, and gives apparently a cross-section of the activities of this group, which is of peculiar sociological interest.

CHARLES H. KEENE

Allergy and Applied Immunology—A Handbook for Physician and Patient, on Asthma, Hay Fever, Urticaria, Eczema, Migraine and Kindred Manifestations of Allergy—By Warren T. Vaughan, M.D., Richmond, Va. (2d ed.) St. Louis: Mosby, 1934. 420 pp. Price, \$5.00.

Vaughan, in his usual story-book fashion, writes a second edition of his book because, as he states, the rapid advance in our knowledge of the subject makes a volume on allergy rapidly become out of date. On this account an old text ceases to be authoritative. What appeared to be a truism of yesterday may be an inaccuracy today. He states that if the text is not up to date it is better out of print.

Vaughan reviews the subject with

reasonable brevity and presents the subject in a way which is amply simple for the general practitioner and can also be understood by patients. He emphasizes the need of knowledge on the part of the general practitioner for diagnostic methods and thinks that with this knowledge he can contribute immensely to the welfare of his patients. Vaughan omits from his book the technicalities on desensitization treatment because of a belief that this is not yet adapted to widespread use by those who are not thoroughly familiar with the subject. This work, he thinks, ought to be diverted to specialists who have acquired enough knowledge and experience with allergic patients to make desensitization therapy successful. Otherwise he thinks such patients are not likely to receive the desired relief which can be acquired through this study and that this practice subjects the entire method to unjust criticism.

Vaughan's book is practical throughout. He discusses in simple manner such topics as diagnostic methods, pollen surveys, location of allergens, methods of allergen avoidance, food allergens and their whereabouts, elimination diets, and the manifestations of allergy. An important chapter, VIII, is devoted to a discussion of geological locations, and the part played by altitude, heat, air humidity, and wind in symptomatology.

The book can be highly recommended as safe and sound for general practitioners and patients.

The printing and make-up of the book are excellent. W. W. DUKE

Healthy Babies Are Happy Babies—Complete Handbook for Modern Mothers—By Josephine Hemmway Kenyon, M.D. Boston: Little, Brown, 1934. 321 pp. Price, \$1.50.

Out of the wealth of experience in instructing mothers and answering their

multitude of questions through the Health and Happiness Club of *Good Housekeeping*, Dr. Kenyon has acquired a facility of presenting subject matter which is a delight to read. She confesses modestly in the preface that it took courage to write another book on child care while she faced three long shelves of similar publications treating every phase of the subject. She has justified her temerity, however, by producing a compact handbook, conveniently arranged for reference, which answer the questions of mothers, and prospective mothers, in clear, concise, "homey" language. The book has a direct, personal appeal which every intelligent mother will appreciate.

The material is arranged in chapters which consider chronologically the important features of each stage in the growth and development of the child, beginning with the prenatal period and extending through the third year. Two helpful chapters on the common communicable diseases of childhood and on emergencies are added to the general plan. The appendix contains a clarification of the usual foods given to children up to 3 years of age, a vitamin table, and foods for different months up to one year of age. RICHARD A. BOLT

Stand Up and Slim Down—By Ettie A. Hornibrook. Garden City, N. Y.: Doubleday, Doran, 1934. 167 pp. Price, \$1.95.

This treatise is devoted to a discussion of the causes and correction of constipation and obesity in women, with the major emphasis on "restoration exercises," the aim being "youthful slenderness, graceful carriage, and poise."

After a brief description of the effects of weakened abdominal and pelvic muscles upon constipation and, oftentimes the resultant marital inefficiency and unhappiness, a considerable portion of the text is devoted to a descrip-

tion of movements and posture in their relation to constipation and bodily health.

Another relatively large section is devoted to a discussion of food selection, as related to obesity and intestinal efficiency.

In the section on movements, there are some excellent postural—including foot, leg, and pelvic—exercises. The effects of faulty shoes, especially too high heels, and the need of proper corset and brassiere are discussed.

This is a much worthwhile book for laymen and physicians. It is made better and more usable by a careful index.

CHARLES H. KEENE

Medicine Marches On—By Edward Podolsky, M.D. New York: Harper, 1934. 343 pp. Price, \$3.50.

The reviewer has always felt some doubt of the value of books of this type, though it must be admitted that the public will read them when they will read no others, and the facts of medical research do need some popularizing. Unfortunately, those who have the facility for popular writing make use of their gift, and intentionally or otherwise, give some wrong impressions. These are sometimes followed up by lay readers by the study of truly scientific books, but more often not.

The book under discussion strikes us as being one of the best of its type. It is unusually complete and the author has evidently kept track of investigation in the field as well as in laboratories. It contains a vast amount of information, practically all of which is correct as far as the reviewer can determine, though as already said, much of it is put in ways which are not pleasing. The titles are almost all dramatic, for example: The Poison-Fighters, Radium Bullets and Crazy Cells, Obesity and the Fat-Melters, etc.

The English as well as the spelling of names could be improved. However,

the book is intensely interesting and we hope that it will serve a useful purpose. Unfortunately, most readers have not the background for judging the exaggerations, overemphasis, etc. There are

many quotations, all in italics, from well known scientists and medical men. The printing is excellent and the paper is light, making it a pleasant book to read.

A SELECTED PUBLIC HEALTH BIBLIOGRAPHY WITH ANNOTATIONS

RAYMOND S. PATTERSON, PH.D.

Rats, Typhus and Relief—Endemic typhus is a serious problem in Alabama and some of the other southern states, thanks to the rat, his fleas, absence of rat proofing, ample food and mild winter climate. CWA rat control is helping.

BAKER, J. N., *et al.* Endemic Typhus in Alabama. Pub. Health Rep. 50, 1:12 (Jan. 4), 1935.

Lead Poisoning—A clinically proved and detailed method is reported upon the control of lead poisoning in which experience counts much for success in administration.

BELKNAP, E. L. Control of Lead Poisoning in the Worker. J.A.M.A. 104, 3:205 (Jan. 19), 1935.

World Health—What the health organization of the League of Nations has done, is doing, and plans to do may seem overly ambitious, but new generations will be amused by its limited vision, this reporter believes.

BOUDREAU, F. G. Health Work of the League of Nations. Milbank Quarterly 13, 1:3 (Jan.), 1935.

Getting Rid of Sewage Sludge—Difficulties experienced in solving the ever present problem of sludge disposal in sewage treatment are set forth in this discussion of modern methods.

CERNY, P. J. Treatment and Disposal of Sewage Sludge. Munic. San. 6, 1:10 (Jan.), 1935.

Practical Tuberculosis Control Economics—About a quarter of the uncoöperative tuberculosis contacts in New Haven (611 persons) were finally induced to submit to an X-ray exami-

nation. In this large group no active cases were found and only a few healed lesions. From this it is concluded that the examination of the contact who consistently fails to coöperate is not worth the expense of the extraordinary efforts needed to get him into the clinic.

EDWARDS, H. R. An Attempt to Secure X-Ray Examination of the Uncoöperative Tuberculosis Contact. New Eng. J. Med. 212, 5:198 (Jan. 31), 1935.

Advice about Buying Food—As an example of suggestions to field workers in educating families to make better purchases of foods, this paper indicates that the method might well be applied to other health educational projects.

FISHER, R. W. What Shall the Public Health Nurse Tell Families about Buying Food? Pub. Health Nurs. 27, 1:11 (Jan.), 1935.

From Settlement to Health Center—A fine, brief story of the development of the neighborhood health service idea and its present-day manifestations.

HISCOCK, I. V. The Development of Neighborhood Health Services in the U. S. Milbank Quart. 13, 1:30 (Jan.), 1935.

When Is Gonorrhea Cured?—Gloomy conclusions about the curability of gonorrhea follow this summary of the criteria of cure which include palpation, culture, complement fixation test, and provocative diet.

KING, A. J. The Criteria of Cure of Gonorrhea in the Male. J.A.M.A. 104, 3:178 (Jan. 19), 1935.

Tuberculosis Work Well Done—The results of the Cattaraugus County Tuberculosis case-finding program are

summarized for the benefit of the world-wide anti-tuberculosis movement. It is emphasized that tuberculosis control can grow at its best only with an adequate public health program.

KINGSBURY, J. A. Methods in Further Control of Tuberculosis. *Milbank Quart.* 13, 1:68 (Jan.), 1935.

Asbestos in Lungs—Lung fibrosis caused by asbestos dust appears to be milder than that produced in silicosis. However, dust in asbestos plants can, and should, be reduced and workers should have periodic physical examinations.

LANZA, A. J., *et al.* Effects of the Inhalation of Asbestos Dust on the Lungs of Asbestos Workers. *Pub. Health Rep.* 50, 1:1 (Jan. 4), 1935.

Incidence of Lead Poisoning—In industrial hygiene studies, when the gastrointestinal diseases outnumber respiratory diseases, suspect the possibility of lead poisoning. This condition is common and often results in wrong diagnoses.

LANZA, A. J. Epidemiology of Lead Poisoning. *J.A.M.A.* 104, 2:85 (Jan. 12), 1935.

Digestion's Time Table—Ordinary meals leave the stomach in 4 hours; a very large one in 5; large amounts of fat delay emptying of the stomach; concentrated carbohydrates leave quicker than natural ones; cooking shortens digestion time for some foods, lengthens others; finally, hunger apparently does not depend upon vigorous peristalsis. These fluoroscopic findings, except the last, confirm accepted beliefs.

MAILE, W. C. D., and SCOTT, K. J. L. Digestibility of Common Foodstuffs as Determined by Radiography. *Lancet.* 1, 1:21 (Jan. 5), 1935.

What Water Can Be Made Fit to Drink?—A basis is proposed for formulating a limited standard of pollution for sources of water supply in the hope that it will stimulate discussion and action by sanitarians.

STREETER, H. W. Limits of Pollution Loadings for Water Purification Systems. *J. Am. W. W. Assn.* 27, 1:1 (Jan.), 1935.

RESIGNATION OF DR. HAYHURST FROM THE EDITORIAL COMMITTEE

EMERY R. HAYHURST, M.D., Ph.D., of Columbus, Ohio, and for seventeen years Associate Editor in Industrial Hygiene on the *American Journal of Public Health*, resigned as of January 1, 1935. This was necessitated because of the demands of his own work. Dr. Hayhurst has been a Member of the Association since 1913, and was elected a Charter Fellow in 1922.

The Committee on Meetings and Publications, in session on Saturday, January 12, 1935, adopted the following:

Resolution

WHEREAS, Dr. Emery R. Hayhurst has served on the Editorial Committee of the *American Journal of Public Health* since 1918, and
 WHEREAS, the Industrial Hygiene interests of the Association have been served by countless pages of material emanating from his pen, and
 WHEREAS, his advice and assistance to the

Editor have been of incalculable value, therefore be it

RESOLVED that the Committee on Meetings and Publications extend to him its warm thanks and deep appreciation for his wisdom, counsel, and continuous labors which have resulted in distinct improvement in the *American Journal of Public Health* and definitely valuable contributions to public health literature.

C. C. YOUNG, D.P.H., *Chairman*
 HOMER N. CALVER
 ARTHUR P. MILLER
 MAZŮCK P. RAVENEL, M.D.
 CHARLES F. WILINSKY, M.D.

The *Journal* has been most fortunate in securing the services of Henry H. Kessler, M.D., of the Department of Labor, Newark, N. J., as Associate Editor in Industrial Hygiene, to take over the work of Dr. Hayhurst. Dr. Kessler has been a Member since 1927 and a Fellow since 1929.

WESTERN BRANCH A.P.H.A.

The Sixth Annual Meeting of the Western Branch will be held in Helena, Mont., July 1, 2, and 3. William F. Cogswell, M.D., Department of Health, Helena, is General Chairman.

APPLICANTS FOR MEMBERSHIP

The following individuals have applied for membership in the Association. They have requested affiliation with the sections indicated.

Health Officers Section

- Emily F. Bolcom, M.D., P. O. Box 1975, Los Angeles, Calif., Medical Director, Women's Venereal Disease Division, Los Angeles City Health Department
- Julius R. Bolles, M.D., Napoleon, Ohio, Henry County Health Commissioner
- Frank C. Cady, U. S. Public Health Service, Washington, D. C., Course of Study, National Institute of Health
- B. Booker Dalton, M.D., Rockingham, N. C., Richmond County Health Officer
- Alonzo E. Hardison, Jr., M.D., Jacksboro, Tenn., Associate Director, Anderson-Campbell County Health District
- E. M. Lucke, M.D., Court House, Hannibal, Mo., Marion County Health Officer
- Emile Martel, M.D., D.P.H., Amos, P. Q., Canada, Medical Director, County Health Unit
- Leo M. Michalek, M.D., Lackawanna, N. Y., Health Officer
- Wu Chi Moy, M.D., Chung Sun Memorial Library, Canton, China, Special Commissioner on Public Health
- Alton R. Perry, M.D., M.P.H., Natchez, Miss., Director, Adams County Health Dept.
- Albert Supple, M.D., 1401 Fair Oaks Ave., S. Pasadena, Calif., City Health Officer
- John M. Uhrich, M.D., Parliament Bldgs., Regina, Sask., Canada, Minister of Public Health
- George M. Wells, M.D., City Hall, Bowling Green, Ky., Director, Warren County Health Dept.
- Thomas B. Wilson, M.D., Box 1296, Longview, Tex., Assistant Director, Gregg County Health Unit

Laboratory Section

- Joseph L. Hileman, M.S., 810 Burnet Ave., Syracuse, N. Y., Chief of Laboratory Division, Dairymen's League Cooperative Assn.
- Robert A. H. Mackeen, General Hospital, St. John, N. B., Canada, Director of Laboratories

Vital Statistics Section

- Halbert L. Dunn, M.D., Ph.D., Univ. of Minnesota Hospitals, Minneapolis, Minn., Director, University of Minnesota Hospitals and Professor of Medical Statistics

Public Health Engineering Section

- Blair I. Burnson, B.S., 2079 Oakland Ave., Piedmont, Calif., Sanitary Department of East Bay Municipal Utility District
- Morgan D. Hayes, B.S., Rm. 52, City Hall, Rochester, N. Y., City Engineer
- William T. Ingram, A.B., 130 S. American, Stockton, Calif., Sanitary Engineer, San Joaquin Local Health District

Industrial Hygiene Section

- C. L. Jones, 1118 Delaware Trust Bldg., Wilmington, Del., Safety and Service Dept., Hercules Powder Co.
- Wendell Stewart, M.D., Murphy Bldg., East St. Louis, Ill.

Food and Nutrition Section

- James A. Berry, M.S., Frozen Pack Laboratory, U.S.B.P.I., Spokane St. Terminal, Seattle, Wash., Research Bacteriologist, Frozen Fruits and Vegetables
- Beth Konkel, Oklahoma City, Okla., Executive Secretary, Tuberculosis Society of Oklahoma City
- Fred V. West, Dr.P.H., 1801 La Cienega, Los Angeles, Calif., Director of Technical Service, Adohr Milk Farms

Child Hygiene Section

- Lester A. Gerlach, D.D.S., City Hall, Milwaukee, Wis., Dental Director

Public Health Education Section

- Fanchon Hart, B.S., 115 W. 68 St., New York, N. Y., Professor of Bacteriology, College of Pharmacy, Columbia University
- A. D. Lapp, M.B., Tranquille, B. C., Canada, Medical Superintendent, Tranquille Sanatorium

Don C. Lyons, D.D.S., 1405 National Bank of Jackson Bldg., Jackson, Mich., Author, Dental Section, Health and Hygiene Column, Univ. of Michigan and Affiliated Organizations

Epidemiology Section

John J. Hanlon, S.B., Department of Health, 3919 John R. St., Detroit, Mich., Statistician

Public Health Nursing Section

Elizabeth P. August, R.N., 50 E. Broad St., Columbus, O., General Secretary, Ohio State Nurses Assoc.

Helen Cochran, State Dept. of Health, State Office Bldg., Richmond, Va., Assistant Director, Bureau of Public Health Nursing

Joseph L. Daniel, R.N., Lawrenceville, Va., Research Worker, U. S. Public Health Service

Unaffiliated

Ralph I. Canuteson, M.D., 1638 Mississippi St., Lawrence, Kans., Director of Health Service, University of Kansas

C. P. Coogle, M.D., U. S. Public Health Service, Houston, Tex., Malarialogist

Reginald O. Davison, M.D., Dept. of Public Health, Parliament Bldgs., Regina, Sask., Canada, Deputy Minister

Sister Mary Edward, Dominican College, San Rafael, Calif., Librarian

Samuel S. Feuerstein, M.D., 42-15 34 Ave., Astoria, N. Y., Physician in active practice

NEWS FROM THE FIELD

BIRTH REGISTRATION CAMPAIGN

THE Bureau of the Census, with the aid of workers on the pay roll of the F.E.R.A., is carrying on a campaign which has for its primary purpose the education of the public regarding the importance of birth registration. Although it involves the post-card check customarily employed by the Bureau, the testing aspect is emphasized only as it relates to intra-state comparisons, the state health authorities being given to understand that there is no thought of checking their eligibility to remain in the registration area, that the purpose, on the contrary, is to assist them in securing the best possible registration within their state.

Campaigns in the following states have been conducted or provided for in the order here given: Georgia, West Virginia, Vermont, New Hampshire, Mississippi, Arkansas, Oklahoma, Missouri, Kansas, Iowa, South Dakota, North Dakota, Montana, Wyoming, Colorado, Utah, Idaho, Washington, Oregon, California, Nevada, North Carolina and Alabama. Other states may be added to the campaign plans in 1935.

In each state there is a publicity director on the F.E.R.A. pay roll, while the Census Bureau provides field representatives, each of whom supervises the checking in from one to three or four states.

One of the incidental benefits of the campaign is that it establishes a direct contact between the Bureau and the state authorities, such as has not always existed heretofore. Another is that it furnishes material for a study of effective methods of promoting birth registration; and also for a study of the problem of securing an accurate check on birth registration. It is expected

that a monograph or report will be prepared on each of these subjects.

In connection with this campaign it developed that a number of states have no adequate indexing of births and deaths, so that searches, if made at all, depend on certificates or journal entries arranged in chronological order. The Census Bureau has it in mind to select or devise a standard indexing procedure which may be recommended to those states which desire to introduce a system of indexing or to improve on one already in use.—A. W. H.

SMILEY HEADS NEW YORK STATE HEALTH EDUCATION

AN outstanding change in management of the health program in the schools in New York State occurred February 8, when Franklin Smiley, M.D., F.A.P.H.A., was inducted as director of the health and physical division of the State Education Department.

Dr. Smiley, who has won wide recognition during his 15 years as director of the health service at Cornell University, will collaborate with Dr. Frank P. Graves and a committee of the board of regents in an effort to improve the health of two million school children in the state. He will have the assistance of associated bureaus in the education department, as well as teamwork from such independent groups as the Mental Hygiene Department and the State Health Department.

In addition to being an author on health and physical education subjects, Dr. Smiley is chairman and secretary of the American Student Health Association and Associate Professor of Hygiene and Preventive Medicine at Cornell.

CERTIFICATE IN SANITARY INSPECTION

THE University of Southern California announces that it is offering courses leading to a Certificate in Sanitary Inspection.

Among the elective subjects suggested for completion of the Certificate are the following: Public health law, inorganic chemistry and qualitative analysis, sanitation and purification of water, organic chemistry, food products, general bacteriology, sanitary science, sanitary engineering, applied psychology, public relations, technical report writing and general zoölogy.

The tuition fee is low, and full information regarding the course may be secured by addressing W. Ballentine Henley, School of Government, 202 Wilson Building, Los Angeles, Calif.

ADULT EDUCATION

THE Tenth Annual Meeting of the American Association for Adult Education (66 East 42 St., New York) will be held in Milwaukee, Wis., May 20-22. Headquarters will be at the Hotel Schroeder. There will be sessions on public schools as adult education centers; adult education in rural communities; adult education under public auspices; vocational education and adjustment for adults; rural library service; avocational interests of adults; training community leaders; readability; and mechanical aids to learning.

Representatives of organizations with adult education programs and all other interested persons are cordially invited to attend the meetings.

TENTH PAN-AMERICAN SANITARY CONFERENCE IN BOGOTA IN 1938

AT the Ninth Pan-American Sanitary Conference held recently in Buenos Aires, it was voted to hold the Tenth Conference at Bogota in 1938.

Surgeon General Hugh S. Cumming, of the U. S. Public Health Service, was

reëlected Director General of the Pan-American Sanitary Office. Dr. Gregorio Araoz Alfaro, of Argentina, was elected Honorary President.

Other officers of the office are Dr. Carlos Enrique Paz Soldan of Peru, Vice-President; Dr. Carlos J. Mongo of Peru, Alternate Vice-President; Dr. Justo F. Gonzalez of Uruguay, Secretary; Dr. Rafael Schiaffino of Uruguay, Alternate Secretary.

Other members of the office are Dr. Solón Nuñez of Costa Rica, Dr. Francisco de P. Miranda of Mexico, Dr. Carlos Diez del Ciervo of Venezuela and Dr. Waldemar Coutts of Chile.

Dr. Jorge Bejarano of Colombia was elected organizing president.

NEW AND BETTER TUBERCULIN AIDS CATTLE-HEALTH CAMPAIGN

A NEW tuberculin, free from foreign protein, has been in use since last April in the testing of cattle for tuberculosis, the U. S. Department of Agriculture reports. The new product is materially superior to the tuberculin formerly available. Officials point out that the improvement came at a particularly fortunate time, since tuberculin testing has been increased as an emergency and drought relief activity, and more cattle have been tested in the last 8 months while the new tuberculin has been available than in any previous similar period of the campaign. Dr. M. Dorset, of the Bureau of Animal Industry, says that enough of the new tuberculin is being produced to test more than 18,000,000 cattle annually. U. S. Dept. of Agriculture, Jan. 24, 1935.

MOTHER'S DAY—MAY 12

A NATION - WIDE Campaign to make maternity safe has been planned by the Maternity Center Association, 1 East 57th Street, New York City. The climax of the effort will be timed for the week previous to Mother's Day, which falls this year on May 12.

PUBLIC HEALTH SERVICE ARRANGES
INSTRUCTION OF COUNTY HEALTH
OFFICERS

THE School of Hygiene and Public Health of The Johns Hopkins University has arranged, at the request of the U. S. Public Health Service, to offer a short course for candidates for appointment as County Health Officer. The course, which began February 6, covers a period of 12 weeks, of which 8 weeks will be spent in intramural work and 4 weeks in the field. Admission has been limited to applicants recommended by the health officers of the states, and appointed by the Public Health Service.

The instruction includes courses in public health, bacteriology, statistics, epidemiology, parasitology, sanitary engineering, and health administration. Dr. H. S. Mustard, Associate Professor of Public Health Administration, is in general charge of the course.—A. W. H.

CHEMISTS NOTE TERCENTENARY

FRANCIS P. GARVAN, president of the Chemical Foundation, has been named honorary chairman of the New York committee which will organize the celebration of the 300th anniversary of the founding of the nation's chemical industries.

The celebration will be held in New York in conjunction with the eighty-ninth meeting of the American Chemical Society, from April 22 to 26. According to Prof. Arthur W. Hixson of Columbia University, general chairman of the committee, more than 10,000 chemists and industrialists are expected to attend the meeting.

NATIONAL NEGRO HEALTH WEEK

THE twenty-first Annual Observance of National Negro Health Week will be from March 31 to April 7, inclusive. For full information, write National Negro Health Week Committee, U. S.

Public Health Service, Washington, D. C.

POPULAR LECTURES ON DOCTORS

UNDER the auspices of the Education Department of the Community Church, 550 West 110 Street, New York, Dr. Philip J. R. Schmahl, Professor of Medicine at Flower Hospital and N. Y. Homeopathic Medical School, will give a series of two lectures on "The Ceaseless Struggle Between Doctors and Death" (illustrated).

SAFETY RECORD

A RECORD of 9,166,135 consecutive man hours, without a lost time accident, is the record set up by the Western Clock Company of LaSalle, Ill. The National Safety Council thinks this is the outstanding industrial safety record of America.—*Am. Druggist*, Jan., 1935, p. 6.

PERSONALS

DR. HARRY B. SMITH has resigned from his position with the Connecticut State Health Department, to accept the position of Superintendent of Health, of West Hartford, Conn., following the resignation of Dr. Theodore F. Foster, member A.P.H.A., due to ill health.

DR. FREDERICK G. NOVY, Dean of the University of Michigan School of Medicine since September, 1933, announced his retirement effective at the close of the current semester. His resignation ends 48 years' association with the institution.

ETHEL JACOBS, R.N., of Albion, Ind., member A.P.H.A., has resigned from her position as Noble County Public Health Nurse to become the 7th E.R.A. advisory nurse on the staff of the Indiana Bureau of Public Health Nursing.

THOMAS J. DUFFIELD, member A.P.H.A., was appointed Registrar

of Records of the New York City Department of Health on January 16. The position of Registrar of Records had been vacant since the retirement of Dr. William H. Guilfooy in 1930 after 40 years of service.

Mr. Duffield brings to the office a varied experience in the field of public health and vital statistics. Following his graduation from the Massachusetts Institute of Technology with the class of 1914, he became Health Officer and Registrar of Vital Statistics in Summit, N. J., a post he left in 1917 to accept a commission in the Sanitary Corps of the Army. From this post, he resigned with the rank of Major, in 1919, after service at Camps Lee and Fremont in the United States, and in the office of the Chief Surgeon of the American Expeditionary Forces in France. He then became Statistician of the Commission for the Prevention of Tuberculosis in France, with headquarters in Paris, and in 1923, after a term as Instructor in Vital Statistics at the School of Public Health, Harvard University, he returned to Europe as a member of the Health Section of the League of Nations.

Returning to the United States in 1925, he served successively with the New York Commission on Ventilation, the New York Academy of Medicine and, since 1932, the Statistical Bureau of the Metropolitan Life Insurance Company.

DEATHS

DR. POWHATAN STANLEY SCHENCK, for 25 years Director of Public Welfare and Health of Norfolk, Va., died on January 24. He became a member of the Association in 1911, and was a Charter Fellow, but because of ill health resigned in 1931. He was 72 years old.

KATHRYN KERSH SCHULKEN, R.N., of

Denver, Colo., member A.P.H.A., died recently. She was Superintendent of the Denver Visiting Nurse Association from 1921 until her death. She was a member of the American Nurses' Association, of the National League of Nursing Education, of the National Organization for Public Health Nursing, and the American Association of Social Workers.

HARRY F. FERGUSON, Chief Sanitary Engineer of the Illinois State Department of Public Health, and member A.P.H.A., died January 16.

CONFERENCES

Mar. 27-29, Canadian Section, American Water Works Association, London, Ont., Canada.

March 31-April 7, National Negro Health Week—21st Annual Observance.

April 3-6, 8th Annual Convention, Southern Physical Education Association, Atlanta, Ga.

Epidemiology of Amebiasis*

J. C. GEIGER, M.D., F.A.P.H.A., G. H. BECKER, M.D., AND
J. P. GRAY, M.D.

Department of Public Health, San Francisco, Calif.

THE epidemiology of amebiasis in these United States has become the source of intense public health interest, particularly in the light of the 1933 Chicago experience. Regarded for many years as a widespread endemic tropical disease, one of the chief obstacles to colonization, and a cause of invalidism to public servants in the tropics, recent years have demonstrated that it is by no means limited to those regions, nor is it the problem it once was in these areas. Any comprehensive systematization of the points published by numerous investigators of the Chicago outbreak of 1933, leaves no doubt of the significant endemicity of this disease in America, and of the fact that public health authorities have a most formidable opponent especially in our older cities or those with large foreign populations of certain types.

Any casual study of the Chicago data brings up most forcibly the attention that must be paid to plumbing with its ubiquitous cross-connections. Previous experiences with this problem in typhoid

fever outbreaks have not entirely accomplished the desired results. Furthermore, the clinician must realize that amebiasis manifests itself in a much broader and more comprehensive picture than is generally allotted to it. Waiting for bloody mucous stools to appear before making a diagnosis and instituting treatment may be responsible for the increasing mortality, since such stools may occur only after considerable damage is done.

Since the discovery of *Entameba histolytica* by Loesch in 1875, autochthonous cases have occurred in various countries and continents. On the Pacific Coast, workers have long agreed that this type of infection is not so rare as is generally supposed, but the reasons for the discordance between frequency of amebic infection and recognition of the disease symptom complex has been a matter of conjecture. Certainly, water or uncooked foods can transmit the disease only when contaminated with fecal matter containing resistant encysted entameba. Epidemiologically, the source of these must be latent cases or carriers. It is accepted that cysts may be passed in large numbers in the stools of carriers, and therefore these probably constitute the

* Read at a Joint Session of the Laboratory and Epidemiology Sections of the American Public Health Association at the Sixty-third Annual Meeting in Pasadena, Calif., September 6, 1934.

most important source of infection. Theoretically, amebiasis is at least a preventable disease, but it is not always practicable or convenient to take into the gastrointestinal tract only substances sterilized by heat.

It is theoretically desirable that all carriers of *Entameba histolytica* undergo treatment, but this may not prove feasible on a large scale, mainly because of the expense involved and particularly because many carriers, despite the technical thoroughness of the examination, may remain undiscovered. With the discovery of the carrier state, the treatment of carriers and their elimination from duties involving the handling of foods served raw, of equal importance is the proper disposal of excreta, since infection is spread through the transference of cysts from the feces to foods and their subsequent ingestion. Evidence has been adduced that cysts may remain viable in fecal matter for 1 week, and that they live longer in the formed than in the liquid stool. Intestinal zoöparasitism in the presence of improper sewage disposal, as cross-connections or siphonage returns from the sewage to water systems, may lead to infections by bizarre methods. Among these may be listed: allowing cyst contaminated water to enter the mouth while bathing, or to enter the rectum as in the use of enemata, or through washing with polluted water the raw vegetables used in salads.

As most modern water systems carry some residual chlorine the work of Bercovitz¹ on the viability of cysts becomes of decided importance. This author worked on the hypothesis that the use of septic tanks in China would solve the problem of the use of human feces as fertilizers, provided the treatment could be modified or supplemented by chemical disinfectants in order to destroy the cysts of intestinal parasites. The cysts were destroyed by 1 per cent solutions of bichloride of mercury or

formalin and by half strength brine after exposure for a maximum period of 1 hour, but not by 1 per cent solutions of acetic acid, chlorinated lime and sodium hydroxide, or by 70 per cent alcohol. The use of hematoxylin stains after treatment was found of more value than eosin in determining the viability of cysts.

The recent work of Spector² and her associates indicates very definitely that the *E. histolytica* cysts are removed completely from water by coagulation and filtration through rapid sand filter beds, and that the amount of chlorine required to kill cysts is much more than could be used in a public water supply. The viability of the cysts in water is therefore of importance. Walker³ and his coworkers kept cysts moist as long as 10 days at tropical temperatures and parasitization subsequently occurred. Darling kept cysts in sterile tap water for 3 days; they degenerated or disappeared and parasitization did not occur in kittens. Schaudinn parasitized kittens with cysts air dried for 6 weeks, but not with those dried for 7 weeks. Dobell⁴ concluded that under artificial (cultural) conditions free ameba of *E. histolytica* may survive room temperature up to 3 days, but at 37° C., may survive for at least 5 weeks. The cysts, however, can remain alive at room temperature for at least 37 days, but usually die within a few days if kept at body temperature.

Presumably water, air, certain temperatures, and the secretions of the stomach provide adverse environmental conditions for the cysts and they will perish if they do not gain access to the human bowel. All cysts do not possess the same viability. The cysts present in carriers' stools may be extraordinarily numerous, a daily output having been estimated to be as high as 3 million, which would permit even microscopic particles to carry the infection. Epidemiologically, the disseminating agents

are food handlers, who carry the infection to food and drink by means of the soiled hands and clothing, transmitting cysts from the toilet to washstand, bathtub, laundry tub, and towel. The cycle would be ideally completed in the presence of cross-connections permitting siphonage between the sewage and the water systems, or by gravity flow through a submerged water supply to a plumbing fixture. Apparently this did occur in the more or less closely associated community which existed in certain hotels in Chicago. The reported absence of other enteric diseases ordinarily associated with water-borne outbreaks involving contamination by sewage, is, however, contrary to epidemiologic expectations. An observation by Musgrave indicated that cold temperatures stimulate the parasite to form cysts more rapidly, and this presumably could occur in the water supplies of hotels, particularly if they are refrigerated. This observation may have to be qualified since he may have been dealing with ameba other than *E. histolytica*.

O'Connor and Weynon, in their work in Egypt, found the largest number of carriers of *E. histolytica* among food handlers and prisoners. The soil under certain conditions may be considered a natural habitat and these authors' findings may be explained on the basis of gross soil pollution and insanitary conditions in the institutions. Vegetables from contaminated soil offer an easy means of dissemination, but this should not occur in the United States.

The cyst carrier offers the greatest problem. It is perfectly true that continuous exposure to carriers occurs quite often without infections, at least without clinical manifestations of infection, and these occasions offer epidemiologic difficulties. For example, a freighter ship recently sailed from Manila in which there were two carriers of *E. histolytica* in the kitchen personnel.

To the crew of 40, there were enroute approximately 9,000 exposures, but in only 1 instance was amebic infection demonstrable; and indeed there is some evidence that this infection may have been acquired ashore.

In this connection, Walker's³ classical experiments in Manila, in which *E. histolytica* was fed to human beings, are of more than passing interest. Of 20 men who ingested *E. histolytica*, 17 became parasitized following the first feeding, and 1 required 3 successive feedings, although all had been prepared with magnesium oxide as a neutralizing agent against the acidity of the gastric secretion. It is doubtful if parasitization would have occurred had they not been so treated. The lapse of time from ingestion of infectious material to the appearance of entameba in stools varied from 1 to 44 days, with an average of 9 days. Of great importance is the fact that of the 18 men experimentally parasitized, only 4 developed dysentery and these were infected with cysts from healthy carriers. The incubation periods were 20, 57, 87, and 95 days. This latency is characteristic of the disease, and such latent infections may follow adjuvant causes, such as fatigue, alcoholic excesses, chilling, etc., but may be entirely due to the chronicity of the ulcerative process. Walker concludes that the chief, if not the exclusive, sources of infection lie in the chronic latent cases or carriers, because of their relative prevalence. Added difficulties arise in the facts that the condition exists indefinitely, the parasitization is unsuspected for years, and the carriers shed continuously or intermittently enormous numbers of cysts.

Kessel⁵ stated that the parasite may at times live in the lumen of the intestine in commensalism and under certain conditions may become a tissue invader; also that it is significant to remember that the entameba living in

the lumen which have ingested bacteria only, when transferred to kittens are invasive and produce dysentery. Moreover, the so-called "small" races of *E. histolytica* produce as severe infections and as extensive pathology as the "large" races, and are therefore probably just as pathogenic. The resistance of the host appears to be a more important factor in the production of clinical amebiasis than the alleged differences in virulence. Higgins asserts that repeated passages increased the virulence but that the accompanying bacteria also played a rôle in the acceleration of the virulence, at least for the production of liver abscesses.

Walker's feeding experiments on human beings were obviously reproduced on a large scale in certain Chicago hotels. Under these conditions, persons returning to their homes throughout the United States were parasitized following their residence in these hotels. It may be significant that no similar outbreak occurred elsewhere and that the epidemiologic problems involved in the spread of the disease and in parasitization were therefore peculiar to Chicago. Perhaps also these conditions were even more limited, being confined to a small area within the city proper. Furthermore, the number of infections in proportion to the number of exposed must have been small, especially when compared to other enteric diseases, or amebiasis is less easily transmitted. The latter hypothesis is probably the deciding numerical infection factor.

Any measurement of the rôle of carriers in the spread of amebic dysentery in a city such as Chicago is unusually difficult. Perhaps, as the epidemiological study and protozoan survey of Williamson, Kaplan, and Geiger,⁶ indicates, the data are unreliable because observations and reports by local physicians are incomplete. Significant data show that amebiasis is by no means restricted to prescribed geographic en-

demic areas. The disease is evidently indigenous to the Middle West, as reported by Brown,⁷ who concludes that "the wide distribution of *Entameba histolytica* must be appreciated by physicians and public health authorities." The problem is inseparably connected with the introduction of large numbers of immigrants from areas in which high parasitic indices obtain. The Chicago data of 1929 are especially interesting in that the carriers discovered were handling food in large hotels, and 64 per cent of them were foreign born. The physician should regard obscure cases of intestinal disease with suspicion and look for the etiological possibility of *E. histolytica*. The health officer has a great responsibility in that he must recognize this problem and initiate appropriate measures for the control of this menace. When such important work as the search for carriers has once begun, no break in its continuity should be permitted.

The importance of this statement is shown in the more recent Chicago experience. The monthly average number of reported cases of amebic dysentery for the City of Chicago is approximately 2, and the annual average for the 3 years 1930, 1931, 1932, was 18. The statistical epidemiologic methods used by the Chicago Department of Public Health are not unlike those of the San Francisco Department of Public Health, which permit of immediate knowledge of appreciable changes in the epidemic indices in the various reportable diseases under observation.

From the published data⁸ the reporting of cases of amebic dysentery in Chicago in 1933 showed nothing of unusual importance until the month of August. The epidemic index as expressed in per cent, or ratio between the normal expected incidence and the actual reported incidence, suddenly mounted to 650, increased to 700 in September, and went as far as 1,400

in October. The very abruptness of this rise in August could have been considered as a warning of no slight significance and an indication for unstinted diligence in rigorous epidemiologic investigation in an effort to discover the probable source or focus of infection. These and subsequent published data of the health authorities in Chicago are ample evidence of this diligence.

Bishop and Bishop⁹ in a study of amebiasis occurring endemically in New York City, concluded that the actual incidence is probably far greater than is commonly supposed, and these authors felt that more attention should be paid to the search for carriers. Faust's¹⁰ data, obtained in protozoan surveys, very definitely indicate the presence of an appreciable amount of *E. histolytica* infection in the population of Wise County, Va., and New Orleans, La. In fact, 4.3 per cent positive specimens were found in 460 persons examined in the former place, and 10 per cent among 172 in the latter.

Reed and his associates,¹¹ in a protozoan survey of 1,000 prisoners at San Quentin Prison near San Francisco, demonstrated 92 per cent infestation. The San Francisco Department of Public Health in coöperation with Reed, has just completed a survey of food handlers in hotels and clubs in San Francisco. Of the 400 persons examined, 3.7 per cent, or 14, were found to be positive for *E. histolytica*. The records failed to show that any of these were responsible for the infection of the cases reported, although careful epidemiologic investigation into the probable source of infection is always made. Also, it should be pointed out, no cross-connections between the sewage and water systems of these hotels and clubs existed.

Previous protozoan surveys made in the United States by Kofoed and his associates, and by Stiles and Boeck,

demonstrated an appreciable amount of parasitism.

The statistical data quoted as a result of observations and protozoan surveys are illuminating but neither conclusive nor exact. The status of the term "amebic dysentery" as to whether reference is made to the carrier state or to a clinical case, is most obscure and perhaps chaotic. Apparently, physicians do not consider the disease as reportable, and even if so, the term "amebic dysentery" is not considered as including the all important carrier state. Obviously, the public health significance of this disease in the United States, with especial reference to the accuracy of statistical summaries of reported incidence, rests with the reports of physicians. That amebiasis is more widespread than once thought or the available reports indicate, should engage the best efforts of the conscientious health officer to determine its real status and danger in the community.

For reliable data, more than one fecal examination in each individual studied is required in every protozoan survey; the same dictum obtains in the clinical diagnosis of the acute case. Furthermore, extreme care must be exercised in the examination of fresh stools and stained specimens for ameba, and full appreciation must be held for the technical knowledge and skill required for recognition of the parasite. In an effort to detect the carrier state, stool specimens from convalescents from amebic dysentery should be examined for *E. histolytica* at frequent and regular intervals. Likewise, the rôle played by the carrier of *E. histolytica*, especially in food handlers in hotels, restaurants, clubs and other public eating establishments still remains an unknown quantity in the epidemiology and spread of the disease in large population centers of the United States, especially where the migration of new immigrants from

known endemic areas is continuous. To these epidemiologic possibilities there has been added through published observations such animal reservoir hosts, as rats, mice, dogs, domestic pigs, and perhaps others, including the monkey. The mechanical transmission by the house fly can be acknowledged but only in areas where the lack of sanitation allows easy accessibility to human feces.

Three matters are of paramount importance, especially in the light of the Chicago experience: (1) the examination of food handlers for the carrier state in amebic dysentery; (2) the probable reason for the localized accelerated virulence; and (3) the administrative problem of proper sewage disposal. Perhaps the carrier state in amebiasis is analogous to what has occurred in the carrier state of other diseases which often has food as its vehicle of infection. The term, "once a carrier, always a carrier," might well have been applied to some of those examined in 1927 in Chicago, and their activities as food handlers forever terminated.

Since the rôle of human carrier has been clearly shown, it would appear that there is ample justification for the search for the carrier state among food handlers as a preventive or control measure. The routine examination of all food handlers presents certain definite difficulties.

The carrier state is frequently intermittent rather than constant. Unless the specimens are obtained under well regulated circumstances, the possibilities of falsification of source are manifestly a possible, and indeed a probable, source of error. The cost of the medical and laboratory examination, if properly carried out to include all possibilities and follow-up, is probably greater than the results of such a search warrant. The expense of setting up a departmental organization, so that the examination may be more nearly uniform

and standardized, is considerable, and official agencies cannot easily demand a fee for such service unless the scope of the examination is extended to include the desirable points of the periodic health examination. In the larger population centers, particularly, such a practice would assume proportions approaching certain types of state or social medicine, and such a program should be avoided. On the other hand, the individualism of medical practice could not supply the public health official with uniform interpretation of findings, and the practice of accepting certificates of private practitioners would not afford the desirable uniformity of standard. The inclusion of the private laboratories, with a certain amount of individualism in technic, also complicates the reliability of the data furnished from nonofficial sources and increases the complexity of the entire program.

The laboratory examination, of itself, offers a greater field of usefulness than the medical examination alone. To be of value, however, the specimens should be from bona fide sources, should have been obtained under controlled conditions, and should be delivered at the laboratory as soon as possible, in good condition, properly labelled. If these circumstances obtained, the results of the laboratory work have definite and important significance; if not, the results of the most careful work are subject to criticism and question. The methods used should be standardized to insure uniform technic, but it must be remembered that the procedures of a decade ago are not suited to present-day requirements. It is highly desirable that the laboratory personnel have an inherent desire constantly to improve the laboratory methods, so that full advantage may be taken of the work of others. Elaborate equipment is not demanded by most improvements in technic, but unless the proper mental

attitude is present in the worker, even elaborate equipment is of little value as an incentive.

Whether food handlers on ships, in hotels, clubs and restaurants should be examined as a prerequisite to employment is open to argument. It would seem more rational that physicians report their cases of amebiasis more promptly and that the Department of Public Health, as the official agency, investigate the probable source of infection with diligence and intelligence, and arrange for the immediate removal of the carrier from food handling, with surveillance over his or her future activities.

The acceleration of the virulence of the organism in Chicago in 1933 appears to be a clinical fact. The reason for this, if it is at all possible to assign any, can be argued only from the evidence which has been presented, on the basis of purely clinical findings and on assumed epidemiologic theories. From the clinical standpoint, the severe type of infection, in which there was reported a high frequency of gangrene of the intestine, with the malignant type of dysentery, would indicate a type of amebiasis heretofore unencountered in the United States. Careful analysis of the detailed tabulations of symptoms and signs and laboratory findings in all cases would be more than interesting. Such data are not available.

Theoretically the apparent epidemiologic exaltation of amebiasis in Chicago may have been due to mass infections or to some superimposed virus of an allied or totally unlike disease. In any event, the Chicago experience may be repeated in other localities and this possibility offers a problem of intriguing complexity to the health official. The determination of the number of permanent carriers resulting should prove of intense interest, for it is highly probable that these will materially increase the inci-

dence of amebiasis throughout the United States.

This increase, however, should not reach even near epidemic proportions in any community, provided the lessons learned in Chicago are not forgotten by health authorities. Moreover, it is not inconceivable that the conditions of cross-connections and siphonage between the sewage and water systems as found in certain hotels in Chicago, or by gravity flow through submerged water supplies to plumbing fixtures, can be duplicated in many communities. The existence of such conditions, however, will stand as an everlasting indictment of the non-enforcement of existing plumbing laws, or demonstrate woful lack of the necessary and essential technical sanitary engineering knowledge which is so remarkable in some departments of public health, even today.

Clinical Amebiasis in Relation to Public Health*

ALFRED C. REED, M.D

Professor of Tropical Medicine, University of California, San Francisco, Calif.

AVAILABLE evidence indicates that between 6 and 12 million persons in the United States are subjects of amebiasis. Such figures at once raise the amebiasis problem to the dignity of major public health interest. From this standpoint, there must be considered the direct death rate, the incidence and mortality of complications, the direct sickness and disability rate, the depression of physical vigor with its concomitant lowering of social and physical efficiency, and the increased susceptibility to other diseases. Data are insufficient to make any fair quantitative estimate of these various items. That the sum total is large and important, can be safely inferred from consideration of the clinical and pathologic features of amebiasis, and from analogy with other widespread chronic diseases such as hookworm infection and malaria. In this presentation it is our concern to analyze the situation and to deduce the best practical methods of control. Amebiasis is considered strictly as human infestation with *Endameba histolytica*.

CLINICAL AMEBIASIS

E. histolytica must be considered primarily, and perhaps entirely, a tissue

parasite. Invasion of the human body takes place solely by ingestion of cysts. In the terminal small intestine, these excyst and release active amebae which tend to invade the mucosa of the colon. Rarely there is invasion of the terminal ileum. Dobell¹ has shown that excystment and encystment can take place in the same surroundings. The first site of election is the cecum. From here the infection may overflow or spread lower in the colon as the amebae are carried along by the colonic flow. They naturally penetrate the mucosa where mechanical conditions favor, as in the flexures, lower sigmoid and rectum.

In the tissue a characteristic pathology is produced by a process of gelatinous necrosis. Callender² describes this as follows:

In both the gland layers and the sub-mucosa the lesions are characterized by the lysis of tissue and the absence of reactive or inflammatory phenomena. . . . While it is possible that the destruction of the mucosa over a considerable area may precede and be the method of formation of the amebic ulcer, the more probable stages in the formation consist in the progression of the amebae to the sub-mucosa along vessels and lymphatics, and the formation of small areas of cytotoxicity (amebic abscesses), their discharge on to the surface, their involvement in secondary infection by bacteria of the intestinal lumen and the gradual extension of the ulcer partially as a result of a secondary infection but particularly as a result of the peripheral lytic action of the ameba. If the secondary infection is of a mild nature, symptoms may be almost entirely lacking. . . . Destruction of

* Read at a Joint Session of the Laboratory and Epidemiology Sections of the American Public Health Association at the Sixty-third Annual Meeting in Pasadena, Calif., September 6, 1934.

a vessel wall by the ameba may lead to a frank hemorrhage, and thus for the first time call attention to the pathological process in the intestine. The principal point needing emphasis is that the amebic lesion is one showing characteristic changes of the activity due to the parasite, cytolysis, and practically no reaction on the part of the tissues until secondary infection occurs when the reactive phenomena are due to that secondary infection and not to the parasite.

The amebic pathology calls attention to 3 clinical points³:

(1) The lesion may penetrate deeply in the intestinal wall, even reaching the serosa. This may result in adhesions, deep pockets and granulomatous masses. It also explains the facility with which amebae may reach the lymph and blood capillaries. (2) Sooner or later secondary bacterial infection of amebic lesions takes place. This leads to important clinical considerations, such as production of fever, complications in symptomatology, lack of clinical cure with specific treatment, and residual, often permanent, bowel damage after eradication of amebae. It also affords a portal of entry for systemic bacterial invasion, thus acting as a true focal infection. (3) The host-parasite balance is of the utmost importance. Granting the presence of amebae, the optimum condition for the host is where the amebic colonies are not extending, and where bacterial infection is absent. The optimum for the ameba is where the bowel is not disturbed in its physiology. Diarrhea and dysentery are easily excited if the amebae become more active. Diarrhea results in decrease or absence of cyst formation and in extrusion of active trophozoites which promptly die. Thus clinically diarrhea is associated with presence of active amebae and disappearance of cysts, causing interference with transfer of cysts to a new host.

The writer⁴ has divided clinical amebiasis into 7 types, based on the pathology already described, which are classified according to the clinical picture and indications for treatment:

1. Dysentery with acute, malignant onset and course—This requires immediate diagnosis and treatment. Fever and prostration are often present and the frequent bowel movements are attended by severe colic and bleeding.

2. Amebic diarrhea or dysentery with sub-acute onset and course—This is the

ordinary type of amebic bowel disturbance. It tends to become chronic or to show irregular exacerbations.

3. Chronic uncomplicated intestinal amebiasis—This includes the so-called "carrier" state, and the condition of recurrent or mildly persistent symptoms. It is the most frequent type in this country. Almost always secondary bacterial infection which requires treatment in itself is present.

4. Extra-intestinal amebiasis, which, for practical purposes, consists chiefly of hepatitis and liver abscess. Abscesses in other organs and ulceration of the skin, especially contiguous to sinuses, are less frequent.

5. Amebiasis complicated by other infections, by systemic diseases, and by surgical conditions—Bacillary dysentery may coexist or the amebic dysentery may mask cancer or colonic tuberculosis. There is reason to believe that amebic lesions may act as true foci of bacterial infection, allowing entry into the circulation of bacteria, bacterial products, and other chemical substances from the large intestine. Surgical complications, including granulomas and abscesses, are not uncommon, especially following the recent Chicago epidemic. Operation in the presence of active, untreated amebiasis is exceedingly dangerous. Proper and safe treatment depends on early diagnosis not later than at the time of surgical intervention in the abdomen. Amebic lesions easily simulate peptic ulcer, cholecystitis, appendicitis, perforation, gangrene and new growth, or they may coexist with such conditions. Operation in the presence of such an untreated amebic lesion is dangerous and may result in fatal perforation or gangrene of the bowel. "It is to be remembered that surgical complications may appear early in a first acute attack, or late in cases insufficiently treated; also that they may be discovered unsuspected at operation, or operated upon without

recognition, or operated upon under a wrong or incomplete diagnosis."

6. Sequelae of amebiasis include various types of chronic colitis, sprue, cancer, chronic infections such as tuberculosis, residual ulcers, and colitis maintained by bacterial infection, and mechanical defects such as stricture and scarring. Effective early treatment is the best preventive for these sequelae.

7. Toxic results of drugs used, must be considered seriously, as all too often an unjustified treatment hazard is added to the disease hazard, as discussed by Anderson.⁵ Toxic drug symptoms must be clearly distinguished from the symptoms of amebic disease.

Together these 7 types make up the clinical picture of amebiasis. This comprehensive picture, based on the pathology and natural history of *E. histolytica* makes the incidence of amebiasis strikingly important in its public health aspects.

Diagnosis of amebiasis is fundamentally important for 2 reasons: (1) On it depends efficient treatment and removal from society of a source of amebic infection. (2) It is the only sound basis for accurate reporting and public health control. Diagnosis rests solely on microscopic identification of *E. histolytica* by a competent technician. Comparatively few technicians are competent to make this diagnosis. It is a procedure definitely requiring special training. A wrong diagnosis is more dangerous than none at all. It should be a part of the general public health program to set up a method of accurate diagnosis, available to all practitioners. Such a method has been described by Reed and Johnstone.⁶ In brief, a thin fecal smear is made on a slide with a small paste brush, and, with care to avoid drying, is put at once in Schaudinn's solution as a fixative. The slides are then sent to a central laboratory, either in Schaudinn's solution or in 70 per cent alcohol, where the iron

hematoxylin staining can be completed and the slide examined. This method has the advantages, (a) of allowing immediate stool examination, thus preserving both cysts and trophozoites; (b) of allowing accurate identification of a fixed preparation; and (c) of affording a permanent slide-record of the diagnosis. The sending of stool specimens by mail is not satisfactory because all motile forms disappear and cysts begin to lose their characteristics after 48 hours.

Treatment of amebiasis has been summarized by Reed.⁴ It is only necessary to note carbarsone as the drug of choice, given by mouth, except in acute dysentery, where rectal use gives quicker control. Vioform has also been used orally with excellent results. In amebiasis of the liver, in surgical complications and for control of malignant acute dysentery, emetin remains the drug of choice. Emetin is dangerous and therefore must always be used with circumspection.^{4, 7, 8, 9} It should never be given intravenously, and the total dosage by any and all routes of administration must not exceed 10 mg. per kilo. Proper treatment of amebiasis depends on correct and early diagnosis. It is essential for public health control and for the immediate as well as the ultimate health of the patient. Every person harboring *E. histolytica* should be effectively treated. This is even more important in chronic, largely symptom-free cyst passers than in acute dysentery because only cysts transmit the infection. The cyst-passer is a danger both to himself and to his fellows.

INCIDENCE AND EPIDEMIOLOGY

James,¹⁰ in 1928, reviewed surveys of the incidence of amebiasis in England, and in North and South America up to 1927. He concluded that the data, so far as presented by authoritative observers, indicated an incidence of 5 to 10 per cent in the general population,

where amebic dysentery is not endemic, and a higher rate where dysentery is endemic. James's experience in non-dysenteric cases was that trophozoites alone were found, without cysts, in 50 per cent. If the same ratio holds in temperate climates as in Panama, James believes that the actual incidence rate, based on examination for cysts alone, should be doubled. He rightly says that a parasite infecting 5 to 20 per cent of the general population deserves attention. He infers that the pathogenicity of *E. histolytica* in temperate climates is inversely proportional to its relative incidence.

Reference may be made to the surveys reported since James's summary (see Table I).

Differences chiefly in methods, selection of groups, geography, and urbanization make it impossible to construct an exact numerical summary of these data. In general they confirm rather than refute James's estimate of a minimal incidence in North America and Europe of 5 to 10 per cent of the general population. For the United States this means a minimum of 6 to 12 million persons infected. In comparison with other infections and parasitic diseases, amebiasis thus assumes major public health importance.

Study of the figures quoted indicates a probable minimal rate in cities and a maximal rate in rural districts. Combined with the experience of the Chicago epidemic, the conclusion seems justified that the incidence of amebiasis is directly proportional to lack of effective disposal of feces. This is related to higher rural incidence and also to city outbreaks which are due to sanitary defects or breakdowns. This general proposition is modified by the influence of contamination of food supplies by cysts from food handlers, by mechanical transfer by insects or dust, and by contamination of foods eaten raw which have been fertilized

with human excreta. These latter methods of infection are results of a personal or individual lapse or breakdown of proper sanitary disposal of feces. We have to consider, then, two major aspects of the public health problem: one concerned with sanitary sewage disposal, both urban and rural; the other with personal hygiene in two particulars—personal cleanliness, especially after defecation, and protection of food and drink from accidental contamination with cysts. The rural problem is much more difficult to control.

It is obvious that every person harboring *E. histolytica* has swallowed human fecal material. For that reason, there is to be expected a correlation between the incidence of other intestinal protozoa, especially *Endameba coli*, and of *E. histolytica*, as has been demonstrated by various workers, in New Orleans by Johns²⁴ and by Faust,²⁶ and in Tennessee by Meleney.²⁵

Experiment and observation agree that transmission of amebiasis is by cysts alone. It has been taught too generally that cysts are found only in formed stools and motile forms only in the presence of dysentery or diarrhea. That this is not true was proved among others by Reed,²⁸ who found in a study of 50 cases in San Francisco that 38 had motile amebae, and of these 3, or 8 per cent, had neither diarrhea nor dysentery. Also in the earlier malignant Chicago cases, cysts were not infrequently found in dysenteric stools. It cannot be assumed that invariably there is no danger of transmission from patients with diarrhea or dysentery, nor that the absence of these symptoms makes certain that only cysts will be passed.

Dobell¹ has shown that cysts of *E. histolytica* can remain alive at room temperature at least 37 days, whereas at body temperature they generally die within a few days. Wight and Wight²⁹

* These cases were consecutive new admissions to the prison, and therefore not "institutional" cases, in which, as Bock and Siles ²⁰ and others have shown, the incidence tends to be higher than in the general population.

have extended Dobell's limit to 46 days. Persistence of viability, however, requires suitable and sufficient moisture. Manson-Bahr³⁰ states, ". . . as cysts of *E. histolytica* can only survive on a moist medium, there is a considerable amount of evidence, experimental and epidemiological, that amebic infection is mostly water-borne." It is known that the cysts may remain viable in water for at least 2 or 3 weeks, while they are easily killed by desiccation, as stated in 1922 by Dobell and Low.³¹ Spector and Buky³² have shown that when human hands were heavily contaminated with infected fecal material and allowed to dry at room temperature, practically all cysts were dead in 5 minutes, and it was exceptional that any survived beyond 10 minutes. It is evident that contamination of food must occur under conditions of sufficient moisture both on the carrying agent and in the food, to prevent drying of the cysts. This emphasizes the importance of washing and drying the hands invariably and immediately after defecation, and of taking particular care to avoid handling moist or liquid foods without this procedure. It throws light on the relation of humid climate to persistence and spread of amebiasis. From this standpoint, amebic incidence becomes a function of the interrelation between humidity of climate, sufficient local moisture to preserve cysts, character of personal hygiene, public sanitary state, and presence of amebic cyst passers. Personal hygiene in turn becomes a function of the interplay of intelligence and sanitary education. In such a summary, it is evident that the easiest natural conditions for transmission will be afforded by accessibility of water supply to cyst contamination, as happened in Chicago. Under such conditions, building up of carrier reservoirs, increased virulence by faster transmission³³ * and mass infection easily

follow and together would seem to explain the epidemiologic and clinical peculiarities of the Chicago outbreak. Here was seen a true epidemic of malignant amebiasis, previously unknown in temperate climates and not fully appreciated in tropical climates. On the other hand, the summary given explains the nearly universal endemic or sporadic occurrence of amebiasis, for it is to be remembered, as Dobell and Low³¹ phrase it, that amebiasis seems to exist wherever there are human beings, and that it is probable that its greater prevalence in warm climates is related more to the question of sanitation than of climate.

We have next to consider the relation of the infected food handler to clinical amebiasis. Such a relation rests chiefly on theoretical and epidemiological grounds. Careful and conclusive studies are inadequate so far to show direct contamination of food under practical conditions by the hands of food handlers. The same remarks apply to the question of family infection.

Milam and Meleney¹⁶ report an intensive study of a rural community in Jackson County, Tenn., including 75 families with 374 persons. These people lived mainly on their own crops, lacked sanitary privies, and were under an isolated, pioneer social organization. Thirty-eight per cent carried cysts of *E. histolytica*. The high infection rate can be correlated directly with the social and sanitary offenses present. Meleney²⁵ carefully surveyed 5 families, comprising 27 individuals of whom

* J. G. Thomson²³ says, "From my experience of this disease, and of all diseases caused by protozoan parasites, I am convinced that the causal organism may vary in its virulence to a very appreciable extent. Further it seems to me that this question of virulence in the case of *E. histolytica* depends to a great extent on the facility and rapidity with which it can pass from host to host. Put shortly, the severity of the disease between the extremes of the acute and the chronic, symptomless, carrier form, is directly related to the frequency with which the individuals in a community are exposed to repeated, intensive and massive infections."

23 were infected with *E. histolytica*. He concluded that the mother was probably the source of spread because she was the chief "food and child handler." He found poor sanitation and hygiene, and low intelligence to be important factors. It would be difficult to say that all amebic patients are of low intelligence but it is certain that a fault in personal hygiene is invariably involved. Where such faults are combined with low intelligence or sanitary ignorance, we see the problem of the infected food handler and housewife assuming major proportions. In all of these situations we come back to the root of the problem in the clinical cyst-passer.

This analysis brings into view two types of clinical control which are potential major public health methods of control: (1) the effective treatment of all amebiasis patients, (2) the perfecting of personal hygiene, including sanitary education, to a point which will reduce the hazard or probability of infection. It is to be remembered that carriers of amebae should be instructed in social hygiene and, in the absence of proper social conformity, should be subjected to restrictive measures, as advised editorially in the June issue of this *Journal*.³⁴ These restrictive measures should at least apply to food handlers and housewives. The problem of control must not be abandoned because of the difficulties involved.

The problem of animal reservoirs needs further study. Monkeys, pigs, and dogs have been suggested by Kessel³⁵ as possible hosts of *E. histolytica*. A survey by Frye and Meleney³⁶ revealed cysts in house-fly droppings and in pigs. Little is known as to the relation to human infection but there is little or no evidence that such transmission occurs or that animal strains are infective for man.

Within the field of epidemiology lies also the question of isolation of patients

and carriers. Here common sense agrees with available knowledge, that isolation is inadvisable in either case.³⁷ Again, personal hygiene and good sanitation are sufficient. Reference must be made to the important and debatable matter of pathogenicity of *E. histolytica*.

We believe that insufficient attention has been accorded to study of predisposition to amebic infection. Craig⁴² in numerous articles, has discussed immunity and complement fixation. It would seem that the obverse is equally important. Various workers as McCarrison,³⁸ and Dunn,³⁹ have called attention to the rôle of deficient vitamin supply in chronic diarrhea and in amebic dysentery. A similar relation to mineral metabolism has received comment by Cantarow⁴⁰ and others. There are sufficient suggestive data to justify a careful, large-scale study, as to the relation between depressed social conditions including unbalanced dietary, and the incidence, and especially the pathogenicity of *E. histolytica*. The bearing on public health is direct and fundamental. Amebiasis may be favored by such factors. In any case, it results in lowering of resistance to other infections and tends to reduce physical and mental vigor. These factors are also related to the extreme chronicity of the amebiasis and its peculiar tendency to exacerbations and relapses. Manson-Bahr⁴¹ states that this may be one of the most persistent of all protozoan infections.

PUBLIC HEALTH CONTROL

It is undoubtedly true, as Milam and Meleney¹⁶ have indicated, that there is little or no correlation between carrier incidence and dysentery incidence, and that amebiasis does not warrant direct special public health measures for its immediate reduction, but this does not at all mean that a definite program should not be formulated for control. Routine examination of all food

handlers for *E. histolytica* is impracticable because of the expense involved, the difficulty of providing sufficient reliable technicians and the uncertainty as to the intrinsic value of the method. Adequate regional surveys of food handlers are much needed in the effort to evaluate the importance of food handlers in spreading amebiasis.

The most important feature of public health control is accurate and complete reporting by physicians of cases of amebiasis. McCoy³⁷ has stressed this point in detail. It is incongruous, to say the least, that the California State Board of Health requires report of "Amebic Dysentery" only, and not of "Amebiasis." Correct reporting is based on availability, and use by physicians, of proper methods for quick and correct diagnosis. The health officer has then to watch his indices of incidence, and follow up any increase of endemic index with an immediate intensive survey of the local area involved. This method seems fully adequate to control the amebiasis problem from the public health standpoint. Its effectiveness rests entirely on accurate and complete reporting by physicians. This in turn necessitates education of physicians in the nature of clinical amebiasis. Too many physicians are ignorant of the clinical and diagnostic features of amebiasis, and its treatment. Until this condition is corrected, control will continue to be inadequate. The old struggle to develop a sanitary sense in the general public must go along with the education of physicians. A popular demand for clean food, clean dishes and utensils, clean kitchens, clean waiters and other food handlers, safe water supplies, absence of flies and insects where food is handled, clean hands and fingers, and the availability and enforced use of sanitary toilets and wash-bowls—such a demand would go far to control the amebiasis problem and with it many other related problems.

CONCLUSION

The incidence, direct effects, and indirect results of amebiasis make necessary a definite public health program with reference to it. This program should consist of (1) education of physicians, (2) education of the public, (3) accurate reporting and close watch of endemic indices, (4) provision of diagnostic facilities, and (5) intensive control of infected areas. Such a program easily coördinates with other health policies and programs and is within the practical range of expense.

Meningitis Quarantine—District of Columbia

ABOUT 1,700 transients were placed under quarantine by health authorities, February 6, because of an outbreak of spinal meningitis, newspapers reported. One death occurred on February 7. About two-thirds of the number were released February 14, but about 300 were still confined because cases had developed in the lodging

houses in which they were quartered. All transient lodging houses were quarantined. About 450 men quartered in small hotels under contract were brought back into the lodges, but those living in private homes were not affected by the ban.—*J.A.M.A.*, 104, 10:840 (Mar. 9), 1935.

Laboratory Diagnosis of Amebiasis*

K. F. MEYER, M.D., AND H. G. JOHNSTONE

*George Williams Hooper Foundation, University of California,
San Francisco, Calif.*

THE recent widespread discussion of amebiasis in both the medical and lay press has again focussed attention on the everlasting importance of correct and early diagnosis. With bewildering frequency new procedures and interpretations have been recommended and the novice is frequently tempted to overcome his shortcomings by trying every method without really acquiring proficiency in one. It is true that the final medical diagnosis is merely aided by the protozoological findings, but in amebiasis the proper identification of the causative organism is of greatest importance. Time and time again such experts as Dobell and James have repeated the axiom: If the microscopic diagnosis of amebiasis cannot be made correctly, then it should not be made at all. Since the diagnosis rests solely upon the microscopic recognition, differentiation, and identification of *Endameba histolytica* in a complex environment, it is obviously essential that those entrusted with the examination shall be competent observers, equipped with special training, technical skill, and experience. The examination for amebae should be confined to certain laboratories staffed with a personnel which can critically study the specimens submitted. Experience and observations during the past 25 years justify the

conclusion that the diagnosis of amebiasis is not the function of the average laboratory.

The essential steps required to make a correct diagnosis may be considered under the following headings: (1) Collection, selection and shipment of material for examination; (2) Concentration; (3) Preparation of stool specimens for examination; (4) Microscopic examination of stained preparation; (5) Cultural examination; (6) Pathogenicity tests; and (7) Complement fixation test.

COLLECTION, SELECTION, AND SHIPMENT OF MATERIAL FOR EXAMINATION

For many years the necessity of studying only absolutely fresh stools has been recognized. This essential prerequisite is usually ignored, and the microscopist encounters many additional difficulties which he would not meet in the study of fresh stool material. In old fecal specimens the motile forms disintegrate, the cysts lose their differential characteristics, and coprozoic forms make their appearance. A large percentage of patients with amebiasis, even in the absence of diarrhea, show motile amebae, together with cysts. Reed (1934) points out that it has been the consensus of opinion that outside of the tropical zone amebic dysentery is infrequently found and that motile forms are associated closely with diarrhea or dysentery; and in the absence of diarrhea or dysentery cysts are to be ex-

* Read at a Joint Session of the Laboratory and Epidemiology Section of the American Public Health Association at the Sixty-third Annual Meeting in Pasadena, Calif., September 6, 1934.

pected. However, in a group of 50 patients he found that 36 per cent showed dysentery and 76 per cent motile amebae. He further points out that if 76 per cent of the cases showed motile amebae, and if stool examination had been limited to cold specimens sent to the laboratory in the usual containers on the same or succeeding days, it is certain that in a majority of the series the diagnosis would have been missed. James (1926) stresses the fact that in about one-half of the histolytica infections seen by him only vegetative forms were found. Motile amebae die quickly and immediate fresh examination of stool specimens or immediate fixation of fresh fecal samples should be resorted to. In an old stool one is apt to encounter numerous active protozoa; it is highly probable that they developed in the stool after it was passed. These are the troublesome free-living coprozoic forms which are introduced into the feces by contamination after passage, or gain access to the alimentary canal in the encysted state, from the air or by the intake of food or water. Andrews (1930) lists 6 members of the Sarcodina and 4 of the Mastigophora which may be encountered in an old stool. To obviate the difficulties enumerated, it has been our practice to have the patient produce the specimen on the premises or in the hospital, and the necessary examinations and preparations are made as soon as possible. In cases where the specimen has to be brought from the hospital or home into the laboratory by the patient, clean paraffined cardboard drug-cans are supplied.

The selection of the proper fecal material for examination is most important. If the stool is not homogeneous, smears should be made from both the formed and unformed portions, and especially from those parts containing flakes of mucus or blood. The evacuation should be normal and not induced by purgatives. Castor and mineral oils should be

avoided as they complicate the microscopic picture. The more drastic purgatives should likewise be avoided, since liquid stools are unsatisfactory—in fact useless. To obtain a soft stool without purgation James (1926) recommends a mild laxative. Kofoed suggests bile salts or *fel bovis*; Haughwout (1930) a full dose of strychnine sulphate, fluid extract of cascara in very moderate dosage or a laxative dose of Carlsbad water, and Reed and Johnstone (1932) Epsom salts in small amount.

An ideal method used many years ago is now again recommended. (Fradkins 1934)—the collection of suitable specimens with the aid of the sigmoidoscope. The proctoscopic examination exposes the ulcers and with a long handled small curette or a camel's hair brush scrapings may be removed which lend themselves to the preparation of excellent slides at the bedside. At times when amebae were not demonstrable in the stools they were found in specimens taken from the scrapings of ulcers obtained through this instrument. Manson-Bahr and Gregg (1921), in view of the fallacies and shortcomings of microscopic diagnosis, advocate the routine use of the sigmoidoscope. Brown (1926), Abd-el-Azim (1930), Paulson and Andrews (1927), and Reed and Johnstone (1932), have all obtained excellent results by the use of this instrument. Willoughby (1928), supporting the practice of sigmoidoscopy, believes that mere swabbing of a lesion is ineffective and holds that amebae can be more certainly obtained by scraping the lesion with a long-handled curette. This procedure deserves wider application since the specimens can be collected at the convenience of the physician.

The shipment of stools to the laboratory should be discouraged. The methods of James, Kofoed, Reed, and Johnstone, which depend on the preparation of wet smears at the bedside,

enable the physician to mail specimens over long distances. Any physician or health worker can keep on hand the few solutions needed and any public health laboratory can furnish suitable containers. Fecal smears prepared directly from the patient are fixed in Schaudinn's solution, then transferred to alcohol, in which they are shipped to the laboratory. For survey work this method is most effective and time saving. It is needless to emphasize the absolute necessity of repeated stool examinations. The number of amebae, both in the motile and cystic phases, occurring in stools from a patient taken on successive days varies to such an extent that it is almost obligatory to make more than one examination. An excellent rule to make at least 6 examinations before a patient is declared free from intestinal protozoa should be adopted.

Manson-Bahr (1921) believes that if a series of cases be examined once each, about one-third of the infections present would be disclosed. In a series examined 3 times, between one-half and two-thirds of the actual number of infections would be detected. Brown (1926), in a survey of 533 cases, found that the positive findings occurred in 68 per cent of the first, 92 per cent of the second, and 98 per cent of third examinations. By using reasonably fresh material and examining the permanent preparations James (1926) expresses the view that in trained hands the positive findings in amebiasis can be raised on the first examination to 75 per cent. According to his experience the second examination, when the first had been negative, raised the percentage to 90. Recently Andrews (1934), in making a comparison of the occurrence of intestinal protozoa from purged and normally passed stools, found that the examination of single purged stools revealed, conservatively estimated, at least 75 per cent of the protozoan species which would have been ulti-

mately discovered, but it must be emphasized that the data published by Andrews were secured by the simple smear test technic with saline and iodine solution and not by the wet-fixed permanent method.

CONCENTRATION

In many instances, cysts occur in fecal specimens in such small numbers that they are detected with great difficulty, and only following the examination of several stools. In order to obviate this difficulty concentration methods have been devised. Yorke and Adams (1926) perfected a simple technic which requires no special reagents. They suggest, in addition, an alternative method for the concentration and washing of concentrate when the cysts are to be used for starting cultures. A much shorter method has been described by de Rivas (1928). The homogeneous suspension of fecal material in 5 per cent acetic acid is mixed with ether and centrifuged. The cysts, if present, will be found in the sediment at the bottom of the tube. This method cannot be used in cultivation work due to the presence of the reagents.

The use of concentration methods as a regular routine procedure, to the exclusion of the more reliable methods (wet-fixed permanent preparations or cultural), is not recommended. Creswell and Wallace (1934), in 1,032 stool examinations used the method of de Rivas followed by the iodine-eosin stain. They admit that although this efficient concentration method was used, perhaps 10 to 20 per cent of the cases were missed. These concentration methods are too strenuous for the vegetative or motile forms which are either completely destroyed or so distorted that recognition is impossible.

PREPARATION OF STOOL SPECIMENS FOR EXAMINATION

In exceptional instances, and then

only when the examiner is an experienced protozoölogist, should fresh unstained stool preparations be employed. James's conclusions that in fresh material a diagnosis cannot be made except by those with long special training who are thoroughly familiar with the elements of microscopy, is amply verified by others. Even the expert may encounter difficulties in identifying *E. histolytica*. If not selectively stained the cells of the inflammatory exudate may be mistaken for amebae.

For preliminary examinations of fresh smears either Kofoed's (Kofoed *et al.*, 1919) modification of Donaldson's iodine-eosin stain or MacDaniels's (1934) methylene blue-methyl alcohol stain can be used. The latter stain is in many ways superior to the iodine and eosin solutions. The whole preparation can be searched with the low power objective in a very short time as the trophozoites and cysts are easily detected as clear refractile bodies in the dark blue field. Under higher power the details of the nuclear structure in organisms stained by this method are more clearly differentiated than in those stained by iodine-eosin. In routine laboratory examinations much time and labor is saved by discarding all stools which fail to reveal intestinal protozoa in the preliminary stained preparation. A definite diagnosis is made on the permanent preparations which have been made from the stool, showing organisms in the fresh smears.

The method of choice in the laboratory diagnosis of amebiasis remains the preparation of wet-fixed, wet-treated, and hematoxylin stained permanent fecal smears.

Comparatively few laboratories make any attempt to prepare satisfactory permanent preparations for the diagnosis of suspected cases of amebiasis. Why this is so is rather difficult to understand as the necessary technic is no more involved and the labor required

no more time-consuming than in many routine staining procedures. The method most commonly used for the preparation of permanent smears is the fixation (hot or cold) of wet smears in Schaudinn's fluid followed by a mordant of iron alum and stained in hematoxylin.*

MICROSCOPIC EXAMINATION OF A STAINED PREPARATION

The microscopic scrutiny of a stained preparation must consider (a) the type of the cellular exudate; (b) the various protozoa which occur in the human intestinal tract, and (c) the plant and animal cells of the food detritus commonly noted in the stools.

The careful examination of the cellular exudate of stools will often prove of invaluable assistance in the diagnosis of amebiasis. In many instances where amebae have not been found on the first examinations the characteristic cellular exudate has indicated their presence, resulting ultimately in the discovery of the organisms. The principle underlying this cytodagnostic method is stated by Haughwout (1930) as, "The cellular exudate from the bowel is a replica of the histopathology of the condition." The basis for comparison and differentiation of the dysenteries (bacillary, amebic, and balantidial) rests on the fact that the cells of the bowel wall react differently to the attacks of the invading organisms. The methods and questions concerned with the cytology of bowel exudates are fully discussed in the papers by Willmore and Shearman (1918), Anderson (1921), Woodcock (1920), Haughwout (1924 a, b, c, 1930), Haughwout and Callender (1925), and lately by Callender (1934).

The inflammatory exudates often contain leucocytes and macrophages containing red blood corpuscles and showing ameboid movement. If not

* For further information regarding procedure consult the author.

selectively stained these macrophages may be mistaken for amebae even by trained workers. The addition of double iodine solution to fresh preparations, in order to tinge selectively the nuclei of the amebae, is not a reliable procedure. Wet fixation and differential staining is indispensable. It is perhaps true that in cases of active dysentery, the large motile trophozoites are readily recognized, but as is generally the case, especially in survey work for latent infections, the precystic or cystic phases predominate. These latter may readily be confused in fresh preparations with corresponding phases of the other species of amebae often found in the intestinal tract concomitantly with *E. histolytica*. In accepting the observations made on permanent preparations as standards, James (1926) concluded that the percentage of error in the examination of fresh specimens with especial reference to the occurrence of *E. histolytica* was too high for accurate clinical work. In fact, it is often difficult to differentiate the amebae even in permanently stained preparations. The permanent preparation has the additional advantage that it serves as an excellent record which can be filed and produced at will.

As stated, the examination of fecal material for intestinal protozoa is not an easy task and the difficulties encountered are numerous. The examination generally resolves itself into determining not what is *E. histolytica* but what is not *E. histolytica*. This statement appears paradoxical but when one considers the countless numbers of objects of both plant and animal origin encountered in a fecal smear, it is evident that the chances for confusion are manifold. *E. histolytica* is only 1 of the 5 species of amebae living in the human intestinal tract; to mistake it in all of its phases for various phases in the life cycles of the other 4 is a simple matter. The intestinal flagellates often are con-

fusing, *Blastocystis hominis*, intestinal epithelial cells, large macrophages containing red blood corpuscles and polymorphonuclear leucocytes are additional pitfalls encountered. Thomson (1926), and Thomson and Robertson (1929) describe and figure in detail the common pseudoparasites occurring in the feces of man which are so puzzling to the observer. Experience is a paramount prerequisite which will protect the examiner from making improper interpretations and grave errors of diagnosis.

CULTURAL EXAMINATIONS

Many workers have stressed the value of the cultivation of *E. histolytica* in diagnosis. St. John (1926) obtained a higher percentage of positive results by culture than by the direct examination of the feces. Craig and St. John (1927), in a comparative survey of 3 methods of examination on 71 individuals, found that the cultural method gave a higher percentage of positives than did either the direct microscopic examination or the sedimentation test. They did not clearly state however, whether the direct microscopic examination was made from fresh smears or permanently by stained preparations. The culture method is of advantage especially when a large increase in the number of amebae is desired. In order to detect cryptic, occult, or hidden infections referred to by Thomson and Robertson (1929) the culture methods may be recommended.

The preparation of the culture media and the making of the cultures are by no means simple. Many media have been suggested. For ordinary diagnostic work Craig's (1930a) simple normal salt-serum medium is satisfactory, but if the cultures are to be maintained for any length of time a medium such as Locke's-egg-blood (L. E. B.) should be used. Kofoed and McNeil (1932) have pointed out the advantages of this for

the maintenance of various species of intestinal protozoa in culture for long periods. The organisms obtained in the cultures must be carefully studied in wet-fixed smears in order to avoid mistakes in diagnosis. Permanent preparations from culture material are difficult to prepare and in routine diagnostic work time consuming. The sediment removed from the culture tube is mixed with a drop of sterile rabbit or sheep serum or a small amount of stool that has been previously shown to be negative for protozoa. Excellent permanent preparations may thus be secured. It is important to note that in studies on the cultivation of *Endameba gingivalis* from the human mouth, Kofoed and Johnstone (1929) found the morphological characteristics of the oral amebae prepared from cultures and stained in permanent preparations decidedly changed. In view of these and similar experiences it is doubtful if the cultural methods offer many advantages over the simple routine procedure of permanently stained preparations of carefully collected stool specimens.

PATHOGENICITY TESTS

Present-day knowledge concerning the pathogenicity of amebae for such remote hosts as the kitten may be of interest scientifically, but the variable incubation time, and the technical difficulties fail to increase the accuracy over the usual diagnostic procedure. As an aid in distinguishing bizarre protozoological findings, the pathogenicity test on carefully controlled monkeys may be considered.

COMPLEMENT-FIXATION TESTS

Mainly due to the studies of Craig it has been demonstrated that specific complement fixing bodies are to be found in the blood serum of individuals infected with *E. histolytica* when alcoholic extracts of cultures of this organism are used as antigens. Craig

(1927, 1928a and b, 1929, 1930b, 1933), in a series of contributions, described the technic employed in the test and the practical application of it in the diagnosis of human cases of amebiasis. He used a human hemolytic system, the sera were inactivated at 56° C. for ½ hour, and the antigen was an alcoholic extract of 48 hour old cultures of *E. histolytica* grown on the Boeck-Drbohlav medium. The test was not considered positive unless a 3 or 4 plus reaction was obtained on a 4 plus scale. Craig (1933) concludes, following an analysis of the results of the test in 1,000 individuals that:

1. Normal individuals, or those suffering from other infections or diseases do not give a positive complement-fixation reaction with the prepared antigen unless there is a coincident infection with *E. histolytica*.

2. The specific complement fixing bodies disappear from the blood serum following anti-amebic treatment and the disappearance of *E. histolytica* from the feces.

3. In relapsing cases of amebiasis the complement-fixation test, which has been negative during the interval of apparent freedom from *E. histolytica*, again becomes positive in rare instances even before the parasite is again demonstrable in the feces. Thus, a negative reaction, unless repeatedly so for several weeks does not prove the absence of amebic infection or that anti-amebic treatment has resulted in cure.

4. The time of disappearance of the positive complement-fixation reaction after treatment resulting in the disappearance of *E. histolytica* from the feces varied between 3 and 28 days.

5. Individuals infested with other species of amebae, or with the intestinal flagellates, do not give a positive complement-fixation unless *E. histolytica* is also present.

6. The complement-fixation reaction

occurs in all stages of amebiasis, but the strongest positive results are usually obtained in symptomless "carriers" or in those presenting mild symptoms of infection with *E. histolytica*. In several cases of very acute amebic colitis the reaction has been doubtful or negative, although in most severe cases the reaction has been positive.

7. The test has proved of value in the diagnosis of cases of amebic abscess of the liver unaccompanied by intestinal symptoms; in the diagnosis of apparently healthy "carriers" of *E. histolytica* and of those presenting atypical or mild symptoms of infection; and in the control of anti-amebic treatment.

A survey of the work of Craig as well as the infrequent studies of other confirming observers shows that the complement-fixation test in amebiasis is highly specific and is of value in the diagnosis of amebiasis especially in the hepatic type and other stages of latent infection. However, one must agree with Craig (1933) when he states:

Where the services of a trained protozoologist are available and it is possible to make repeated microscopic examination of the feces in suspected cases, this test would be of comparatively little help in diagnosis, as I am convinced that every case of intestinal infection with *Endameba histolytica* can be diagnosed by microscopic examinations of the feces, provided repeated examinations are made, if necessary.

The practical application of the complement-fixation test is greatly limited. The preparation of an efficient antigen is difficult as cultures have to be continuously maintained over long periods to supply the necessary material. In addition Craig (1929, 1930b) has pointed out that not all of his extracts possessed antigenic properties. He often obtained inert extracts from the same strain of *E. histolytica* that had previously given, and afterward gave, excellent antigenic extracts although the inert ones were made in the same manner as the active.

SUMMARY

1. The following axiom must be recognized: If the microscopic diagnosis of amebiasis cannot be made correctly it should not be made at all. Since the diagnosis rests solely upon the microscopic recognition, differentiation and identification of *Endameba histolytica* in a complex environment, it is obviously essential that those entrusted with the examinations are competent observers equipped with special training, technical skill, and experience. In fact, it is recommended that the examinations for amebae be confined to certain laboratories properly equipped, and with a personnel which can critically study the specimens submitted. The diagnosis of amebiasis is not the function of the average laboratory.

2. Although the experts have recognized for many years the necessity of studying only absolutely fresh stools, this essential prerequisite is usually ignored. In old stool specimens, the motile forms disintegrate, the cysts lose their differential characteristics, and coprozoic forms make their appearance.

3. Equally important is the selection of the proper fecal material for examination. The evacuations should be normal. If not otherwise obtainable, a mild purgative may be used. Liquid stools are unsatisfactory and useless. It is important that different portions of the stool be selected in the preparation of the smears. This is particularly desirable when stools of variable consistency are submitted for examination.

4. With the aid of the sigmoidoscope, specimens may be secured admirably suited for a search for amebae. The proctoscopic examination exposes the ulcers, and with a long handled small curette or a camel's hair brush scrapings may be removed which lend themselves to the preparation of excellent slides at the bedside. This method deserves wider application.

5. The shipment of stools to the laboratory should be discouraged. The methods of James, Kofoid, Reed, and Johnstone, which depend on the preparation of wet smears at the bedside, enable the physician to mail specimens to the laboratory over long distances. Fecal smears prepared directly from the patient are fixed in Schaudinn's solution, then transferred to alcohol in which they are shipped to the laboratory. For survey work, this method is most effective and time saving.

6. It is needless to emphasize the absolute necessity of repeated stool examinations. At least 6 successive daily examinations should be carried out before a patient is declared free from infection.

7. In exceptional instances, and then only when the examiner is an experienced protozoologist, should fresh unstained stool preparations be employed. The method of choice in the laboratory diagnosis of amebiasis remains the preparation of wet-fixed, wet-treated and hematoxylin stained permanent fecal smears. Selective or differential staining of the wet preparation is most essential. The majority of modern methods have fully taken care of this aspect of the diagnosis.

8. The various concentration methods may be useful in the hands of a skillful worker. They are time consuming, and since they rarely surpass in accuracy the wet-fixed preparations or the cultural methods, they have no place in the regular routine examinations.

9. In order to detect cryptic or hidden infections, the cultural methods may be recommended. The preparation of the culture media and the making of the cultures are by no means simple. The organisms obtained in the cultures must be carefully studied in wet-fixed preparations in order to avoid mistakes in diagnosis. By comparison, it is doubtful if the cultural methods offer many advantages over the simple routine procedure of permanently stained preparations of carefully collected stool specimens.

10. The microscopic scrutiny of a stained preparation must consider—(a) the type of cellular exudate, (b) the various protozoa which occur in the human intestinal tract, and (c) the plant and animal cells of the food detritus commonly noted in stools. Experience is a paramount prerequisite which will protect the examiner from making improper interpretations and grave errors in diagnosis.

11. Present-day knowledge concerning the pathogenicity of amebae for such remote hosts as the kitten may be of interest scientifically but it fails to increase the accuracy of the usual diagnostic procedure. As an aid in distinguishing bizarre protozoological findings, the pathogenicity test on monkeys may be considered.

12. The complement-fixation test, although specific and of value in the diagnosis of hepatic amebiasis and various other stages of latent amebic infection, is technically exceedingly difficult. Its use is limited on account of the great variability of the antigenic extracts and other irregularities inherent to the complement-fixation test of protozoan infections. One must agree with Craig, who believes that the fixation test is not needed provided a trained protozoologist can examine repeatedly properly collected and stained stool specimens.

ADDENDUM

METHOD FOR STAINING FECAL SMEARS WITH IRON-HEMATOXYLIN

1. Smear is made with a paste brush on a clean flamed slide.

2. Without allowing slide to dry immerse it immediately in the fixing fluid (Schaudinn's).

3. For fixation and staining the following methods should be used:

Minutes

Schaudinn's fluid heated at 60°... 10

or overnight at room temperature.

70% alcohol tinged to a wine color with a saturated solution of iodine in absolute alcohol or with Lugol's solution 10

70% alcohol 5

50% alcohol 5

35% alcohol 5

Tap water (running) 2

Distilled water—rinse

2% iron alum—aqueous solution heated to 30° 10

Tap water (running) 10

Distilled water—rinse

0.5% hematoxylin—aqueous solution heated to 30° 10

Tap water (running) 5

Distilled water—rinse

Minutes

Differentiate in 2% iron alum heated to 30°

Tap water (running) 20.

35% alcohol 5

50% alcohol 5

70% alcohol 5

95% alcohol 5

100% alcohol 5

Carbol-xytol 5

Xylol 5

Mount with a thin layer of balsam thinned with xylol for temporary slides or with thicker balsam and cover slip for permanent slides.

Schaudinn's fluid—Two parts of saturated aqueous Hg Cl₂ in normal salt, 1 part 95% alcohol. This is the stock solution and will keep indefinitely. Add 4 c.c. of glacial acetic acid to 96 c.c. of the stock solution on using. This solution should be made up fresh at frequent intervals.

Hematoxylin stain—Hematoxylin must be properly ripened in order to secure satisfactory results. The best method is to prepare a stock solution of 10% hematoxylin in 100% alcohol. This solution should be corked and allowed to stand in the light for 3 months or

more. The stain—a 0.5% solution of hematoxylin in distilled water—is then made by using 1 part of stock solution to 19 parts of water.

Iron-alum—The ferric ammonium sulphate crystals must be clear and purple or lavender. Yellow crystals should not be used. Make a 2% solution in distilled water.

Carbol xylol may be used in the place of absolute alcohol if the absolute becomes con-

taminated with water; or in handling large numbers of slides it may be used between absolute and pure xylol. (Two washings of toluol may be substituted for the carbo-xylol and xylol.)

Carbol-xylol—Fill wide-mouthed bottle one-third full with clear white crystals of carbolic acid and then fill rest of bottle with xylol. If crystals are yellow or brownish in color the preparation will be discolored.

DISCUSSION OF AMEBIC DYSENTERY PAPERS

F. W. O'CONNOR, M.R.C.S.

Department of Medicine, Presbyterian Hospital, Columbia University, New York, N. Y.

THE frequency of family incidence of amebiasis has engaged the attention of many workers for years. Much may be learned from these "amebic families," as may be illustrated by the study of one such family in Chicago which consisted of 10 members. One daughter had dysentery; the father and another daughter gave a history of recent diarrhea with the occasional passage of blood and mucus. One of the younger sons was found to be losing weight although he complained of no other symptom. On stool examination every member of this family was found to harbor *E. histolytica* cysts and the same sized strain of cyst—about 10 micra—was found in each case. Since we have encountered many amebic families we make it a point invariably to question patients with dysentery regarding the health of the other members, and when suggestive histories are forthcoming, we generally endeavor to examine the other members of the same family. Our object is to prevent the dissemination of infection by these potentially dangerous families. In another respect study of families is desirable when possible, namely, in cases of a patient's relapse after treatment. Since the treatment of amebiasis still leaves much to be desired relapses after any known form of treatment occur in a small percentage of cases. Sometimes

however, there is evidence that the apparent failure to cure is more probably due to reinfection from some other member of the family.

It would appear that at last amebiasis is recognized to be a public health menace in this country. Such being the case it is necessary that in at least the laboratories of state health departments recognition of the causative parasite should be possible. Much has been both written and said to leave the impression that the parasite can only be recognized by a few protozoal experts in certain laboratories of this country. While it is true that long and careful training is necessary before a student becomes a competent protozoölogist or helminthologist with a knowledge of the bionomics, methods of transmission, immunity reactions, etc., of parasites, nevertheless the recognition of the various intestinal protozoa and the ova of helminths may be acquired by any competent technician, at any laboratory where there is abundant fresh material, under one of the recognized teachers.

Several laboratories are engaged in teaching such technicians and find that the average laboratory worker can, within 3 weeks to a month, acquire sufficient knowledge in this field to enable him to render valuable service in diagnosis on return to his unit.

Potential Problems of Industrial Hygiene in a Typical Industrial Area*

J. J. BLOOMFIELD, F.A.P.H.A., AND W. SCOTT JOHNSON, F.A.P.H.A.

*U. S. Public Health Service, Washington, D. C.; and Sanitary Engineer,
Health Division, St. Louis, Mo.*

REALIZING that the improvement of the general health status of the industrial worker is a public health problem and as such should be one of the functions of a department of public health, the health officials of one of the industrial areas in the United States decided to inaugurate a program of industrial hygiene. These officials also realized that one of the first steps in such a program is to obtain a comprehensive conception of the extent of the problem as it exists today. Such a conception, in the absence of definite industrial morbidity and mortality statistics, may be approximated by a preliminary survey of the industrial establishments of the locality, which should be of a type which would reveal the number of persons employed in the various occupations; the materials, processes and conditions associated with these occupations; and the welfare facilities afforded the workers in the industrial environment; thereby yielding a definite picture of the working conditions.

Fortunately, an opportunity to conduct such an investigation in a comparatively brief period was offered through the agency of the Civil Works Act, whereby it was possible to employ

some 40 engineers for this problem. In order to conduct this survey in a standardized manner and under the guidance of experienced personnel, the aid of the Office of Industrial Hygiene and Sanitation of the U. S. Public Health Service was enlisted.

This report deals with the results of this study, and also contains definite recommendations for a program of industrial hygiene for the health department in the area surveyed. It was not possible to evaluate by exact quantitative methods the extent of exposure of workers to various materials and the effect of such exposure on the health of the workers, since this would have required a number of persons trained in industrial hygiene. For this reason, it must be kept in mind, that *the results presented in this report must not be interpreted as indicating in any manner whatsoever that an exposure to an industrial condition or material necessarily implies injury to a workman, but merely indicates the potentialities of the situation.*

METHODS USED IN STUDY

Prior to undertaking the survey, the prospective investigators were given lectures on industrial hygiene in general, and particularly on the technic involved in conducting preliminary surveys. With the aid of 2 simple survey forms investigations were made in 615 plants.

* Read before the Public Health Engineering Section of the American Public Health Association held at the Sixty-third Annual Meeting in Pasadena, Calif., September 4, 1934.

The shorter of the 2 forms dealt with data pertaining to the plant as a whole, and required such information as the kinds of products manufactured, number and types of buildings, and a "yes" or "no" answer to certain questions relating to industrial welfare provisions, and whether or not disability statistics were kept at each plant. The longer form, dealing specifically with each individual workroom, was designed for recording the type of work performed in the room, the lack or presence of certain kinds of sanitary facilities, the presence of potential exposure to accidents, fumes, and gases, other poisons, dusty processes, and the various occupations and activities of each occupation. These forms were so worded that the investigator had to use his own judgment very little, most of the data being supplied by the plant management, since it was realized that even with the short instruction course given the men, they were still inexperienced in industrial hygiene methods. In view of the uniform manner in which the data were collected, it is felt that the information, as far as it goes, represents the actual state of affairs existing in the various plants at the time this survey was conducted.

The work of each investigator was checked daily and the results were immediately coded on forms prepared for this purpose. At the end of the field study, which consumed about 7 weeks, the coded results were tabulated in the field for statistical analysis.

RESULTS OF SURVEY

Table I shows the number of male and female workers employed in the various plants at the time this study was made. For the sake of simplicity, the different plants are grouped into 10 main industries. Of 28,686 workers covered in this survey, 22,610 (78.8 per cent) were males. The survey covered roughly about one-third of the

persons working in all the manufacturing and mechanical industries in the area, giving an adequate sample of the industrial population under consideration. The industries are arranged in the order of the number of plants found in each industrial group, which in all but one case (the leather industry) also meant in the order of the number of persons employed. By far the greatest number of plants and persons were found in the metal products industry, which accounted for 41 per cent of the plants and 48.7 per cent of the workers.

The percentage distribution of the plants according to the number of employees shows that nearly half (48.7 per cent) of the plants employed less than 10 workers, while 10.2 per cent had 100 or more. The leather products industry, mostly shoe factories, contained the greatest number of plants with 100 or more workers (34.8 per cent). In a few instances, the number of employees totalled close to 1,000; such large plants were frequently found in the metal products industry. At first thought, one would be inclined to conclude that this study included too many small plants, that is, those employing but few workers. However, an examination of the data obtained by the U. S. Census of Manufacturers,* shows that the so-called "small plant" predominates in our manufacturing industries. The percentage distribution for 210,959 manufacturing plants included in the 1929 Census shows an even larger percentage of plants with less than 10 workers than found in the present survey; in the United States, 55.0 per cent as contrasted with 48.7 per cent in the area surveyed. On the whole, the distribution for the plants studied compares very favorably with the manufacturing plants in the United States, indicating that the establishments surveyed were quite representative from the standpoint of numerical size.

* Personal communication.

INDUSTRIAL WELFARE PROVISIONS

Many public health workers and industrialists will concede that a program for the prevention of accidents and disease among the industrial population is a most rational plan. In fact, it is now well understood that the fostering of such programs for minimizing the hazards incidental to employment, is in reality a far-seeing economy. Such programs rightfully come under the heading of industrial welfare, an activity which contributes both to the social and industrial progress of any community. In view of the far-reaching and favorable influence which such activities have been known to exert in the industrial picture, it was deemed necessary to obtain some information on the extent of the industrial welfare provisions in the plants under consideration.

The information on such provisions as safety supervision, medical and nursing facilities, sick benefit associations and disability statistics, disclosed some very interesting facts. Only 5 per cent of the plants and about 20 per cent of the workers were provided with the services of either a part- or full-time safety director and most of these supervisors were found in the plants with 100 or more employees. The medical and nursing care was found to have about

the same status as the safety work. Seventeen per cent of the workers had a part-time medical supervisor and only 15.3 per cent had the services of a full-time physician. Full-time nursing service was found to be present for 34.1 per cent of the employees, with practically no part-time nursing service. The only type of disability statistics existing to a great degree in the plants under study, was that of accident records, the keeping of which is compulsory by the provisions of the State Compensation Act. Sickness records were kept for 40 per cent of the population studied, most of such records existing in establishments having sick benefit associations.

In an attempt to determine the influence of the small plant on the data relative to the industrial welfare provisions, Table II was constructed. This table shows the percentage of plants and employees having certain welfare facilities, in establishments employing 100 or more workers as contrasted with similar data for plants with less than 100. (It was found that 89.8 per cent of the plants had less than 100 workers.)

It is apparent that for practically all the listed industrial welfare facilities discussed, the larger plants had a greater percentage of workers furnished

TABLE II

INDUSTRIAL WELFARE SERVICE IN PLANTS WITH 100 OR MORE EMPLOYEES AS COMPARED WITH PLANTS HAVING LESS THAN 100 PERSONS

Kind of Service	Per Cent of Plants and Employees with Listed Service			
	Per Cent of Plants		Per Cent of Employees	
	100 or More	Less than 100	100 or More	Less than 100
Safety Organizations:				
Safety Director:				
Part-time	25.4	2.7	28.1	6.4
Full-time	29.9	2.2	32.4	6.0
Shop Committees	44.5	6.5	42.2	16.0
Other	73.0	81.6	66.4	86.4
Medical Provisions:				
First Aid Room	53.8	4.9	66.0	12.6
Plant Physician:				
Part-time	19.0	1.4	23.1	5.4
Full-time	11.1	0.2	22.7	0.1
Plant Nurse:				
Part-time	3.2	0.4	5.3	2.0
Full-time	31.7	0.2	50.5	0.3
Disability Statistics:				
Sick Benefit Association	38.1	3.4	39.4	8.9
Sickness Records	49.2	13.3	49.4	20.7
Accident Records	100.0	78.6	100.0	93.9

with such provisions; however, even some of these larger plants were somewhat lacking in medical and nursing service, safety directors, and disability records. It is superfluous to comment at length on the data in Table II, since the information speaks for itself. However, it is desired to point out that in this area, as well as in the United States as a whole, about half of the plants employ less than 10 persons, and 90 per cent less than 100 workers. It is the so-called small plant, therefore, that is predominant, and as this survey has revealed, it is this size plant which was lacking in those welfare provisions which play a vital rôle in any constructive program of industrial hygiene. For this reason, and others that will be developed later, a program of industrial hygiene carried on by a department of health—one that will reach the small as well as the large plant—will be a means of furnishing the services now needed in industrial establishments.

SANITARY PROVISIONS

Although insanitary conditions may not necessarily be associated with ill health, it has long been recognized that the elimination of sources of uncleanness in factories is conducive to the general well-being and efficiency of the workers. For this reason, an attempt has been made to appraise the sanitary facilities of the industries studied by recording the various provisions of a sanitary nature.

In spite of the voluminous writings disseminated on the dangers of spreading disease by the use of the common drinking cup and the common towel, 19.5 per cent of the workers were using the common drinking cup and 13.0 per cent the common towel. In the printing, electroplating, clay, glass and stone, and dyeing and cleaning establishments, about half of the workers were using a common cup, and in some of these same industries the common towel was also tolerated.

POTENTIAL ACCIDENT HAZARDS

An analysis of the data on accident hazards showed that unguarded moving machinery was the most common potential source of injury, 41 per cent of the workers being exposed to this type of risk. Floor hazards ranked next, with 13.2 per cent exposures, while 7.5 per cent of the workers were not protected against the possibility of eye injuries from flying particles.

Our investigation did not allow for an analysis of accidents experienced in the various industries, so that it is not possible to draw any definite conclusions from the data, except to point out that additional precautions should be taken by the officials to eliminate some of the potential sources of accidents disclosed. That such exposures may at times lead to actual injuries is illustrated by the data in Table III, which shows the percentage distribution of compensated cases by specific causes in certain industries in the State of New York for 1931,² as compared with corresponding percentages based on potential accident hazards revealed in the present survey. Only industries and causes common in both surveys were compared, so that it was necessary to omit some material from both studies. It is obvious that a striking relationship exists between the percentage distribution of potential accident hazards and com-

pensated cases for nearly all the causes shown in Table III.

In concluding this portion of the study, one additional table is presented on the possible benefits which may be derived from a closer supervision of safety work. Table IV shows the number and percentage of workers exposed to unguarded moving machinery in plants having either a part-time or full-time safety director, and compares these data with the findings for plants not having such safety supervision. It is apparent that in 4 of the largest industries under consideration (embracing 88 per cent of the total population studied), the percentage of workers exposed to this type of potential hazard was in practically every instance much higher in the plants not having a safety director than in those plants provided with one.

OCCUPATIONAL EXPOSURE TO SPECIFIED MATERIALS AND CONDITIONS

It is well known that numerous materials and conditions incidental to industrial processes are causative factors in the production of occupational diseases. Dublin and Vane,³ list some 94 groups of industrial poisons in the United States, associated with about 900 different occupations. In view of the influence these materials and conditions may have on the health workers, one

* Plants having part-time or full-time safety director are compared with those not having such personnel.

of the most important tasks undertaken in the present inquiry was the recording of raw materials, processes and finished products associated with each occupation encountered in the 615 plants under consideration. Some 50 varieties of materials and conditions were encountered, of which 11 may be placed in the category of a minor exposure, since experience has shown that no cases of systemic poisoning have ever been associated with the handling of these 11 materials. It should be pointed out again, that the *data on occupational exposure to these materials and con-*

ditions, must not be interpreted as signifying that the workers were being subjected to toxic amounts of hazardous materials, for no quantitative studies of the workroom environments were made. The data merely indicate the potentialities present in the plants studied.

Space does not permit a detailed discussion of the results of the occupational exposure to materials and conditions disclosed in this survey. However, an idea of the extent of the problem is afforded by the results shown in Table V, which gives the number and percentage of exposures (not workers,

TABLE V

NUMBER AND PERCENTAGE OF EXPOSURES TO SOME OF THE IMPORTANT MATERIALS DISCLOSED IN SURVEY

Materials	Number of Exposures	Per Cent of Exposures
Inorganic Non-metallic Dusts:	7,862	27.4
Emery Dust	3,678	12.8
Quartz Dusts	2,585	9.0
Carborundum Dust	793	2.8
Other Silicates	403	1.4
Talc Dust	204	0.7
Asbestos Dust	199	0.7
Carbon monoxide	5,538	19.3
Lead compounds	2,926	10.2
Benzol	1,544	5.4
Turpentine	1,124	3.9
Benzine	995	3.5
Methanol	881	3.1
Aniline compounds	863	3.0
Cyanides	561	2.0
Ammonia	477	1.7

since a worker was exposed at times to more than one material) to some of the important materials found. Inorganic, non-metallic dusts, of which there were 6 varieties, had the largest number of exposures, 7,862 (27.4 per cent). Carbon monoxide came next, with 19.3 per cent of the workers exposed, while lead compounds accounted for 10.2 per cent of the total exposures. The other materials and their corresponding figures are listed in this table. It is evident that from the viewpoint of the kind of materials offering possibilities for future study, inorganic non-metallic dusts of the type listed, carbon monoxide and lead compounds are the ones associated with the greatest percentage of exposures (57 per cent). The problem as to materials and number of exposures is certainly indicated quite clearly in Table V.

In order to form an idea of the entire problem concerning the handling of various materials in the plants covered by this survey, the data in Table VI were prepared in a manner to show the number and per cent of contacts in the 5 major industries, using only those ma-

terials in which the exposures were 10 per cent or more. It is quite clear that in the metal products industry dusts of the types listed in Table V, carbon monoxide, and lead compounds constitute the major potential problems; in the printing industry lead compounds, carbon monoxide, aniline compounds, and benzine are of importance from the standpoint of the population covered; whereas in the chemical plants the list includes dusts, lead compounds, aniline compounds, turpentine, manganese compounds, and benzine. In the clay, glass and stone industry only one substance stands out—dust, while in the leather products industry benzol is apparently the only material of importance from the viewpoint of the number of exposures. It is apparent that dust is still one of the most important materials of industrial hygienic significance, with carbon monoxide, and lead compounds closely following. It is of signal importance to point out that, at least so far as the remainder of the United States is concerned, the largest number of cases of occupational poisoning have been due to these same materials. It

TABLE VI

MATERIALS IN THE FIVE MAJOR INDUSTRIES IN WHICH THERE WERE 10 PER CENT OR MORE EXPOSURES

<i>Industry</i>	<i>Materials</i>	<i>Per Cent of Exposures</i>	<i>Number of Exposures</i>

is the feeling of the writers of this report that the problem confronting the health officials and industrialists of this area is made manifest by the results of this study.

RECOMMENDATIONS

The preliminary survey of the industrial establishments reported indicates that a large part of the industrial population surveyed is handling materials, and is associated with processes and conditions of manufacture which, if not properly controlled, may lead to injury and ill health of the workers. It is the feeling of public health workers that the improvement of the general health status of the industrial worker is as much of a public health problem as the control of communicable diseases, or any other phase of preventive medicine. As a result of the numerous studies conducted on the health of industrial workers by the U. S. Public Health Service, as well as other agencies, it is established that morbidity and mortality rates are higher for the industrial than the general population, and that certain occupations are of first importance as factors in the causation of excessive sickness and mortality rates.

That the general health of the worker in industry is affected by the materials, processes, and conditions incidental to employment, aside from what we already know of the rôle played by specific occupational diseases, is interestingly presented by Dublin.⁴ In evaluating the effects of the industrial environment on the well-being of a large number of workers in a mortality study among $3\frac{1}{4}$ million white, male wage earners, he found that the mortality rates for the industrial workers were from one and one-half to more than double those for the non-industrial workers. In terms of life expectancy the industrial worker at age 20 had an expectation of life of 42 years as compared to 49 years for the 20 year old non-

industrial workers, or a decrease of 7 years. It is Dublin's feeling that although heredity and innate differences play some part, probably the most important factors are the conditions incidental to industrial employment, such as toxic gases, dusts, specific occupational poisons, extreme temperature variations, and many other industrial hazards.

When one considers the size of the industrial population of the region covered in this study, and the results of this survey on a representative sample of the industrial population, in which the potentialities of occupational hazards are clearly brought out, the possibilities of the situation are quite evident, and certainly merit the attention of the local health department.

We know the effect on the human body of various communicable diseases, such as typhoid, smallpox, diphtheria, etc., and take the necessary measures to control them. The effect on health of certain toxic materials used in industry is also known, and it would seem logical to take appropriate measures for the control of these occupational diseases. We know about some of the toxic materials and processes which may affect health. For example, it is known that exposure to more than 20 million particles of granite dust (35 per cent quartz) per cu. ft. of air will in time cause silicosis of a disabling type, usually followed by tuberculosis⁵; that the breathing of more than 1.5 mg. of lead per 10 cu. m. of air, in the form found in lead storage battery plants, will in time lead to serious types of plumbism.⁶ In short, if these various materials and processes are not controlled, they will affect the health of the individuals exposed to them, and in the case of a disease such as tuberculosis, others in the community may be affected.

It may be said that occupational disease problems should and could be

solved by industry itself. It is the feeling of students of this problem that such a procedure is no more feasible than the attempt of an individual to control communicable diseases in his own home, or industry the pollution of streams. Industrial hygiene is now recognized as a major public health function, affecting directly the health of a large population and indirectly the well-being and economic status of the entire community. The fact that industry will benefit by the control of occupational diseases, should be considered as merely incidental. No industry is large enough to employ the personnel and facilities necessary for industrial hygiene work, and one must not lose sight of the fact that in the present case, as well as in the country in general, the largest percentage of the industrial population is employed in small plants (nearly 50 per cent of the plants studied employed less than 10 persons), and the greatest need is for these small plants which are incapable of dealing with their problems individually. A health department, with its commissioner, epidemiologist, public health nurse, sanitary engineer, bacteriologist, chemist, laboratory technicians, etc., all in one compact unit, is the only practical body equipped to conduct work of a preventive nature in industry.

The practice of industrial hygiene (control of occupational diseases) falls largely within the province of two types of workers, the physician and the engineer. It is within the sphere of the physician to diagnose occupational diseases and primarily to recognize the existence of those diseases due to the factory environment. Based on the findings of the physician, the engineer is in a position to learn where control measures should be initiated. The engineer's work consists of studying the local plant conditions which have been shown to be detrimental to health, and evaluating the various methods which

may be designed for controlling the hazards. It is impossible to tell by a mere inspection of a workroom whether toxic materials are present in the air in such quantities as to constitute a hazard, and whether the protection afforded is adequate. Precise quantitative measurements are needed. Once these measurements have been made, the engineer is able to determine definitely the extent of the hazard and the necessary remedial measures.

In order to carry out a constructive program of industrial hygiene the minimum requirements are:

(A) A physician thoroughly trained in public health procedure and one having a comprehensive knowledge of the effects upon health of the various materials and processes used in industry; in other words, one trained in industrial hygiene.

(B) An engineer who is also trained in industrial hygiene and who is familiar with industrial processes. He should know the following subjects from both a theoretical and practical viewpoint:

1. Microscopy
2. Gas chemistry
3. Mechanics of ventilation
4. Physiology of ventilation
5. Industrial sanitation
6. Illumination
7. Industrial hygiene survey methods

(C) A completely equipped laboratory for carrying on studies in industry. With such personnel and facilities, the following program could be inaugurated:

1. Reporting of all occupational diseases to the division carrying on industrial hygiene work. This will definitely establish where and to what extent certain occupational diseases are occurring, and to suggest corrective measures.

2. In order to acquaint industry, the medical profession, and others interested in such a program, it may be necessary that the personnel carry on an

educational campaign, designed to instruct and interest the various groups involved, as to the importance of the problem, in an effort to further the program. It has been the experience of health departments that the best way to conduct work in industrial hygiene is to coöperate fully with industry, conducting studies in plants, as a rule, only upon request of industry. At the completion of such studies a confidential report on the results should be presented to the plant officials, with recommendations for the improvement of conditions, if such information is necessary and available. All this should be made very clear to the individuals concerned, in order to obtain the coöperation and aid necessary for such work.

3. Studies of the workroom environment and the health of workers by the industrial hygiene personnel as outlined in 2.

4. In order to carry on this work with the minimum amount of friction and in a spirit of coöperation, it may be necessary to provide a law or regulation which specifically states that the results of any investigation made by the health department can in no way be used in litigation, either by the employer or by the employee. The need for such a ruling is obvious if the interests of all concerned are to be served justly. Attention is called to the Act under which the Bureau of Occupational Diseases of the Connecticut State Department of Health functions, as well as to the ex-

cellent work this Bureau is accomplishing in the control of occupational diseases in that state.⁷

The additional cost for maintaining industrial hygiene personnel of the number and type given would not exceed \$10,000 a year, or slightly more than 1 cent per capita in the present case. When one realizes the fact that one case of silicosis often costs more than the \$10,000 needed for a preventive program of the type outlined, the financial phase of the problem should certainly not preclude the establishment of such a vital adjunct of a health department in a large industrial center.

In closing, it is well to emphasize one important point: namely, that occupational diseases are in a large measure preventable, and the degree of prevention exercised by a community will be reflected in the general health status of that community.

The City Health Officer Looks at Diphtheria Prevention*

HUNTINGTON WILLIAMS, M.D., Dr.P.H.

Commissioner of Health, Baltimore, Md.

MORE than a decade has now been spent in many communities in organizing and improving campaign measures aimed toward the ultimate local eradication of diphtheria. Although a health officer may learn much of value in studying the procedures in use in various other parts of the country, each one must eventually work out a machinery of his own, based upon and deeply rooted in local circumstances. By these I mean the community inheritance of relationships between the health department and such groups as the medical profession or other official or nonofficial health agencies, as well as the inheritance in statutory responsibility placed directly upon the local health department itself.

A diphtheria prevention program organized to meet the conditions existing in Baltimore might go on the rocks in a mid-western or western city and *vice versa*. Of course this does not mean that there are not many procedures and methods which will work successfully, wherever applied.

In Baltimore the City Code of Ordinances, in specifying the duties of the Commissioner of Health (there is no Board of Health in our city), includes the statement:

It shall be his duty . . . to make diligent inquiry into all cases of malignant, in-

fectious or contagious diseases which may occur, and cause immediate measures to be taken to arrest their progress. . . .

Similar responsibility is placed upon boards of health in many localities, as for instance in one of our larger cities where the Charter specifies that the Board of Health—

. . . shall, so far as is possible, prevent and suppress the spread of infectious and contagious diseases

and in another city where the Charter provisions require the Board of Health—

. . . to use all reasonable means for ascertaining the existence and cause of diseases of peril to life and health and for averting the same.

To my mind, with such definitely fixed legal responsibility as exists in our city, the health officer and the health department should never abdicate or turn over to any other person or group the mechanics of such a program as diphtheria prevention but, with the least expense on his budget, should organize his antidiphtheria fighting forces with only one thought in view, namely, what methods will most rapidly result in the practical eradication of diphtheria from the community, or in other words, what methods will most rapidly achieve the protection of the greatest number of children at about the age of 6 months.

Quite properly, primary attention is needed in securing as far as is possible, the whole-hearted support of the local medical profession in a civic diphtheria :

* Read at a Special Session on Diphtheria Immunization of the American Public Health Association at the Sixty-third Annual Meeting in Pasadena, Calif., September 4, 1934.

prevention campaign. As a rule, the medical profession expects or should expect leadership in health promotion from the health department; on the other hand, no health officer should fail to indicate to the medical profession that the health department cannot do its job along modern lines without the active support of the local medical fraternity. The health officer needs this positive support and has the right to expect it and to receive it. None the less, he must also earn it by indicating an appreciation of the problems facing the medical profession and by showing an earnest desire to serve the profession in a firm but friendly way. It is my experience that slight modifications of inherited and sometimes troublesome health department procedures often play a tremendous part in winning the coöperative support of physicians. It was our good fortune, in 1932, to have the following resolution adopted unanimously by the *Baltimore City Medical Society* on the recommendation of its own Committee on Public Health and Relations:

The Committee on Public Health and Relations after a full discussion of the problem, diphtheria immunization, believes that the best interests of the community could and would be better subserved by the *Baltimore City Medical Society* requesting the Health Department to put on a campaign on diphtheria immunization and that the physicians of the city coöperate with the Health Department to that end. Also wherever individuals or families, because of their impaired circumstances, are unable to pay for the service that the Health Department be asked to render the necessary immunization gratis.

Similar resolutions were adopted at the same time by the three other medical societies in the city.

The machinery for community diphtheria prevention, like all other public health work and human relationships in general, requires a pretty ample supply of what I like to refer to as "oil and grease," which must be applied at the

right time and in the right places, if success is to be achieved.

I have noticed that diphtheria prevention efforts may languish for lack of adequate financial support. I do not think a health department can undertake an antidiphtheria campaign in any adequate manner if special funds are not set aside for this particular work. An immunization program merely added to routine health department activities is often unfruitful. We have been fortunate in having during recent years from \$1,000 to \$1,400 a year for our annual diphtheria prevention campaign. This is in addition to a considerable sum spent on toxoid which, of course, should be supplied by the Bureau of Laboratories without cost for use in private medical practice.

It has been helpful to focus the major community attention on diphtheria on May Day, or Child Health Day, although this year the opening of the *fourth annual campaign* has been postponed until October 1, because of the presence of a widespread city measles outbreak during April and May. The campaign does best, however, if it is continued throughout the year, and it has been our custom to begin with the New Year an effort "to skim off the cream" of the diphtheria prevention practice and steer it into the offices of the private practitioners. Our publicity for the first 4 months each year places the main emphasis on securing one dose alum precipitated toxoid inoculation for all children at the age of 6 months, or as soon thereafter as possible, and from the family physician. Public clinics are open throughout the entire year, however, and with the city-wide publicity campaign launched by a proclamation from the Mayor on May 1, the Health Department, with its medical and public health nursing forces, conceive it to be their duty to "mop up," so to speak, in the clinics every possible child that has not been inoculated

by that time. In describing our campaign efforts, including the focus on steering diphtheria prevention work into doctors' offices, before a luncheon club made up largely of lawyers and business men, I was struck not long ago by the comment of a lawyer who said his profession would be fortunate in having some governmental agency doing as much for them.

Of course the newspapers probably are the greatest single help in the publicity, although the radio and a minute-and-a-half talkie trailer shown in the motion picture houses throughout the city are among the other most valuable adjuncts.

This movie talkie trailer, created by our Health Department with the aid of volunteer guild actors was seen during May, 1933, by an estimated audience of about one-half the city population. It is based on a special 6 months personal greeting card, which is sent by the Health Commissioner to about 35 Baltimore babies each day throughout the year, and every year, on the day they reach the age of 6 months. Promptly following its mailing there is a follow-up visit by a public health nurse. The card has on it the picture of a child of about the right age, and the message is one wishing the baby the best of health and happiness and urging particularly that the parents protect the child by toxoid inoculation without delay. The assistance of the Public Health Committee of the City Medical Society was sought in the wording of this important message, which reaches practically all of the 14,000 babies born each year in our city. Among other things the message states

We hope your parents will plan *now* to protect you against diphtheria.

Surely, if you could talk you would ask them to do this for you. Maybe the next time you cry your Mother or Father will understand that you are begging for their help and will take you to a doctor who will give you the safe and harmless toxoid inoculations,

or refer you to one of the Health Department clinics.

The movie talkie trailer, which is entitled "An Ounce of Prevention," depicts the postman leaving the message at Mrs. Kelly's doorstep, addressed to the Kelly baby, who is 6 months old on that day. Two more scenes indicate Mr. and Mrs. Kelly going into a huddle over the matter and Mrs. Kelly then taking the baby to Dr. Brown for toxoid inoculation.

Just this year, in May, we adopted 1 c.c. of alum precipitated toxoid as the standard immunizing agent for our city and we expect that a larger number of children will be protected because only one dose is necessary. In former years with two-dose toxoid about 12 per cent of the children receiving the first dose failed to return for the second one. This change from the two-dose toxoid was made after a local research study and in consultation with the authorities at the U. S. Public Health Service.

With us the entire community focus on diphtheria prevention is set at the age of 6 months "or as soon thereafter as possible." It has always appeared to me that if a health department states merely that the preschool age is the desirable period for inoculation, without saying anything more definite, the average parent will procrastinate until the child is nearly ready to go to school, and much valuable time will thereby be lost. The constant reiteration of 6 months as the desirable age has, I believe, resulted in an earlier average inoculation age in our community than would otherwise have been the case.

The selection of 6 months as the age of choice for toxoid immediately brings into focus the fact that the Schick test, except for occasional sampling of the child population, is of no practical administrative value in a program aimed at the younger preschool children. It is for this reason that I am

constantly amazed at the reluctance with which some administrative health officers approach the decision of throwing the Schick test overboard as a health department procedure. The *Appraisal Form* may in part have been responsible for this. I know that a few of my scientific friends are saddened by this feeling I have, which is quite a strong one, that the health department's job is to expend all its energy on getting more and more 6 months old babies inoculated. With the dramatic reduction in diphtheria in recent years following widespread immunization, the question of exactly what percentage of inoculated children may or may not be Schick positive after varying intervals of time should be a matter of only academic interest to a health department. It may possibly be that 10 years from now we will be sorry that we have not done Schicks on the thousands of children inoculated in Baltimore, but I am extremely doubtful of it and believe that the Schick test is a time consuming and expensive interference in a clear-cut city diphtheria prevention campaign where the age group focused upon is made up of 6 months old children.

By periodic letters to the medical profession twice a year, by the use of business reply cards for reporting children inoculated, which are sent out with these letters and are also distributed with the toxoid from the Bureau of Laboratories, the Health Department has been fortunate in receiving an increasing number of reports of diphtheria prevention work in private practice. In 1932 the ratio of protected children reported by medical practitioners as compared with those inoculated at the clinics was 1 to 16; whereas in 1933 there had been a relative increase in the work done and reported by physicians, so that the ratio then stood as 1 to 6. For the first 7 months of 1934 the ratio has been 1 to 4. Of course the 1934 campaign,

opening in October, will probably alter this last ratio somewhat.

The Parent - Teacher Associations throughout our city have organized diphtheria prevention committees and home visiting groups and have been of the utmost assistance in persuading parents, during the active part of the campaign, to have their children protected. Similar work has been carried on by our well organized Negro civic groups. The school authorities likewise have been most coöperative, and many industrial concerns have placed in their pay envelopes special pink health department slips urging the toxoid inoculation of children in the families of the employed groups in industry. During the 1932 campaign these same slips were also sent out with each telephone bill in the residential areas during the month of May. Many collateral forms of publicity have been helpful, including out-door posters, placards inside and outside of trolley cars, displays in conspicuous downtown store windows, and articles in a score or more of special local periodicals, including the foreign language press. The new poster in use this year was drawn by a high school girl in a city-wide school art class competition.

The message the year around and emphasized particularly during the month of May is shown opposite.

It is difficult to appraise the exact results of an effort of this kind but we have set for ourselves the goal A Year Without a Death from Diphtheria in a city of over 800,000 population. The case and death rates have come tumbling down in recent years with these active diphtheria prevention campaigns. In 1930, 17 per cent of our preschool population had been reported as inoculated; in 1932, the percentage was 24; and in 1933, it was 31 per cent. In 1930 there were 20 diphtheria deaths in our city, which was the lowest figure on record at that time. In 1932,

PARENTS! TOXOID PREVENTS DIPHTHERIA
SEE YOUR PHYSICIAN

OR

VISIT A DIPHTHERIA PREVENTION CLINIC

PROTECT YOUR CHILDREN AT THE AGE OF SIX MONTHS, OR AS SOON
THEREAFTER AS POSSIBLE

there were 15 deaths, and in 1933 there were only 6 deaths; whereas so far this year we have already had 5 deaths. The diphtheria death rate for the year 1933 was 0.7 per 100,000 population.

There may be years when the rates will go up a bit, but if our continuing efforts are adequate there should never be a return to the conditions of the pretoxoid era.

Diphtheria Immunization Record

THE largest number of diphtheria immunizations in any year since 1929, 185,586, was reported by Dr. John L. Rice, Health Commissioner (New York City), for the year 1934. Of the number of children immunized 117,569, or 64 per cent, were under 6 years old. In 1929, when the Diphtheria Prevention Commission began its intensive drive, 211,985 children were immunized. Since this commission ceased to func-

tion in 1931, the work has been carried on by the Health Department without outside funds. In 1932 there were 166,243 immunizations; in 1933 there were 161,611.

Deaths in the 3 year period 1932-1934 fell to an average of 133 per year, contrasted with 750 when the demonstration was begun in 1929.—*Medical News* (New York City), *J.A.M.A.*, Mar. 2, 1935, p. 757.

Diphtheria Immunization by One Injection*

V. K. VOLK, M.D., D.P.H., F.A.P.H.A.

*Deputy Commissioner, Oakland County Department of Health,
Pontiac, Mich.*

A STUDY was made of the time required for development of immunity and the degree and frequency of reactions which follow the use of toxoid.

The various preparations of toxoid administered intramuscularly to a large group of Schick positive children were:

1. New York City toxoid, $8\frac{1}{2}$ units per 1 c.c.
2. New York City toxoid, $8\frac{1}{2}$ units per 1 c.c. to which 0.2 per cent alum was added
3. Michigan toxoid, $7\frac{1}{2}$ units per 1 c.c.
4. Alabama alum precipitated toxoid, 10 units per 1 c.c.
5. Michigan alum precipitated toxoid, 20 units per 1 c.c.
6. New York City alum precipitated toxoid, 42 units per 1 c.c.

Results obtained with two injections were described previously,¹ but are presented briefly for comparison.

In a group of 359 children, two 1 c.c. injections of $8\frac{1}{2}$ units of toxoid produced 93 per cent immunity at the end of 12 months. In a group of 337 children, two 1 c.c. injections of a similar preparation, modified by the addition of 0.2 per cent of alum, produced 95 per cent immunity in the same period, and showed a more rapid development of immunity during the first few months.

In a group of 229 children, two 1 c.c.

injections of concentrated toxoid of 30 units per c.c. produced 86 per cent immunity at the end of 12 months. Reactions following the use of this preparation were 3 times more frequent than from toxoid of lower potency. The results obtained with alum precipitated toxoid were determined by re-Schicking at the end of 6 months those children found to be positive at the end of 6 weeks.

Another group of 173 children were given the Schick test 6 months following administration of one injection of alum precipitated toxoid from 3 laboratories; the percentage of Schick negatives was slightly lower than those obtained at the end of 6 weeks, the figures being: Alabama 66 per cent, Michigan 69 per cent and New York 71 per cent.

Although a somewhat higher percentage of negatives was expected among the group of children previously Schick tested, the lack of correlation was apparent between these groups and invited investigation as to the duration of the immunity.

A group of 170 children who were Schick negative 4 to 6 weeks after receiving one injection of alum precipitated toxoid of either 10 or 20 antigenic units, were tested after 6 to 7 months. Of this group previously Schick negative, 16, or $9\frac{1}{2}$ per cent, had become positive.

* Read at a Special Session on Diphtheria Immunization of the American Public Health Association at the Sixty-third Annual Meeting in Pasadena, Calif., September 4, 1934.

TABLE I

SUMMARY OF RESULTS OBTAINED WITH ONE INJECTION OF 1 c.c. OF TOXOID

Preparation	Units per 1 c.c.	Number of Children in Group	Per Cent Schick Negative at End of:				
			4 Weeks	6 Weeks	8 Weeks	6 Months	12 Months
New York City Toxoid.....	8½	220	40	..	57
New York City Toxoid modified with 0.2 per cent alum.....	8½	388	47	..	61
Michigan Toxoid	7½	217	42	..	61
Alabama alum precipitated Toxoid	10	290	64	73	..	84	..
Michigan alum precipitated Tox- oid	20	239	62	72	..	83	..
New York City alum precipitated Toxoid	42	193	65	73	..	86	..

McGinnes and his coworkers² found the reversion of Schick negatives to Schick positives took place in 5.6 per cent of 342 children. Another group of 71 children who were Schick negative 4 to 6 weeks after receiving one injection of alum precipitated toxoid of 42 antigenic units showed reversion of 3 per cent to Schick positive when retested after 6 to 7 months. The age group of children showing reversion of the Schick test runs parallel with the age distribution of the entire group.

Ten of the 18 children who showed reversion of the Schick test were retested 6 weeks later, and at the same time blood was taken from 7 for the purpose of ascertaining the antitoxin concentration.* The results of these tests are shown in Table II.

It may be seen that 7 children showed an increase in their immunity status by the stimulus of the preceding Schick test injection and that 3 out of 7 had antitoxin above the so-called immunity level of 0.03.³

REACTIONS

The frequency and degree of reactions have been partially reported.¹ A detailed questionnaire was sent to the parents of all children who received one

of the toxoid preparations. Over 66 per cent of the questionnaires were returned and it is reasonable to assume that there were no moderate or severe reactions among those who failed to reply.

While we are aware that the parents' interpretations of reactions might not coincide with the clinical picture, we consider them of importance because they reflect the parents' observations.

Table III, which represents an analysis of over 1,100 replies, shows the per cent of reactions in the entire group of children regardless of age.

When analyzed by age group, reactions are found to be much less frequent in the age group under 8, reactions increasing in frequency as age increases.

Attention is called to the occasional occurrence of general reactions immediately following the administration of the Schick test in children who had previously received the Schick test and toxoid. These reactions previously described,¹ while of short duration, were of sufficient severity to justify alarm over the character of the attack, which resembled anaphylaxis.

Another case of severe reaction was observed on November 27, 1934. A boy, age 5, had a preliminary Schick test with controls on April 6, 1934, which was read on April 11. At that time he received 1 c.c. of alum pre-

* Antitoxin concentration was determined through the assistance of Dr. W. E. Bunney of the Michigan Department of Health.

cipitated toxoid. When retested on May 28, the child was Schick negative. On November 27, together with many other children he was again retested to study the frequency of reversion of Schick tests. In less than 15 minutes after the test, while the author was on his way to another school, the nurse noticed that the child had developed urticaria and redness over his entire body, swelling of the face and severe

pain in the epigastric region. In this case there was no shortness of breath and though he was generally distressed, he did not require the administration of adrenalin. A similar case of severe reaction has been reported by Shiffrin.⁴

Though these reactions are fortunately rare, they tend to serve as a restraining influence in the acceptance of toxoid as the preparation of choice. Undoubtedly the repetition of the Schick

TABLE III

PER CENT OF REACTIONS FOLLOWING 1 C.C. INJECTIONS

Preparation	Units per 1 c.c.	Per Cent Having No Reaction	Local			General		
			Per Cent Mild	Per Cent Moderate	Per Cent Severe	Per Cent Mild	Per Cent Moderate	Per Cent Severe
New York City Toxoid..	8½	26	65	8	..	20	3	1
New York City Toxoid modified with 0.2 per cent alum	8½	28	67	7	..	28	6	1
Michigan Toxoid	7½	33	63	3	..	12	8	1
Alabama alum precipitated Toxoid	10	24	70	6	..	24	4	..
Michigan alum precipitated Toxoid	20	27	69	4	..	22	3	..
New York City alum precipitated Toxoid... 42		12	86	2	..	38	1	..

test was a contributing factor, but elimination of the test could scarcely be offered as a solution of the problem. Bunney's⁵ opinion on the subject is of interest:

The results suggest a very definite need for a study of the Schick test following immunization with alum precipitated toxoid. If an injection of toxoid in contrast to a toxin-anti-toxin injection, renders a certain number of children sensitive so that an injection of diphtheria toxin in the Schick test causes shock, and perhaps in some individuals a false straight positive reaction; then it might very well be possible that an injection of alum precipitated toxoid, in which the toxoid is being absorbed from the site of injection over a considerable period of time, would result in a larger number of such sensitized children.

CONCLUSIONS

1. Analysis of the results obtained clearly indicate the superiority of alum precipitated toxoid as an immunizing agent.

2. Preparations of higher potency make only a moderate difference in the percentage of children developing a negative Schick reaction.

3. Local and general reactions are

more frequent in the preparations of higher potency.

4. Immediate reactions which follow the administration of the Schick test in previously immunized children deserve most careful study.

5. The duration of immunity effected by alum precipitated toxoid needs careful investigation. It is possible that preparations of higher potency may confer more lasting immunity.

6. The creation by the American Public Health Association of a committee to evaluate the results of the studies made by a large group of workers in the field of diphtheria prevention will be a helpful factor in acquiring more facts and better knowledge of what may be expected from the use of alum precipitated toxoid.

Potability of Water from the Standpoint of Fluorine Content *

H. V. SMITH

University of Arizona, Tucson, Ariz.

MOTTLED enamel was first described in the United States by Black and McKay¹ although it had been described in 1901 by Eager,² who found it in Italian immigrants. Their findings seemed to point to local water supplies as responsible. It was not, however, until 1931 that it was found to be due to fluorine in the water. The proof³ consisted of giving water which was known to cause human mottled enamel to rats, and also feeding to other rats small amounts of sodium fluoride. In both cases mottled enamel was produced. Added proof in the way of chemical analysis showed low concentrations of fluorine in waters not associated with enamel and high concentrations in waters which had produced the defect. Churchill⁴ added further evidence by analyzing waters from several parts of the United States. High fluorine contents were found in certain endemic regions.

METHODS OF FLUORINE ANALYSIS

Since our proof of the causal relationship of fluorine to mottled enamel, the question of potability of water from the standpoint of its fluorine content has become of prime importance. Lack of accurate methods of fluorine analysis

has impeded progress in determining the toxic level.

At the time the original investigation was made in 1930 the most promising method available was that of Ross, Reynolds, and Jacob,⁵ in which dry silicon tetrafluoride was distilled into water and the resulting hydrofluosilicic acid determined by titration with a standard base. Using this method in a limited number of analyses, it appeared that waters containing 2 p.p.m. or more of fluorine were associated with mottled enamel as its cause. A year later an extensive investigation⁶ was carried out in Arizona for the twofold purpose of disclosing endemic areas in the state and obtaining evidence from analyses of water supplies from both endemic and non-endemic areas by which it would be possible to determine definitely the concentrations of fluorides in drinking water which interfere with normal enamel development.

Since the volatilization method did not lend itself well to routine determinations, another method of analysis was sought, and the Fairchild method was selected. In this method ferric iron in excess is added to the fluorine containing water. The iron combines with the fluorine, probably forming a complex ion. The uncombined iron is then determined iodimetrically and the amount of fluorine present calculated.

The survey disclosed about 45 towns or rural districts in Arizona in which

* Read at a Joint Session of the Laboratory and Public Health Engineering Sections of the American Public Health Association at the Sixty-third Annual Meeting in Pasadena, Calif., September 4, 1934.

mottled enamel is endemic. Analyses of 110 public and 75 private water supplies show a fluoride content ranging from 0.0 to 12.6 p.p.m. Concentrations above 2.7 p.p.m. were found to be definitely toxic, that is, always associated with mottled enamel in its consumers.

Because of the great interest in this problem, several more sensitive methods for fluorine determination have been developed recently, and the Fairchild method has been shown to give results which are far too high.

The methods of Foster⁸ and of Armstrong⁹ both depend upon the removal of fluorine by the addition of an excess of ferric chloride as in the Fairchild method. The uncombined iron is determined colorimetrically, Foster using ammonium sulphocyanate and Armstrong acetylacetone.

Foster has also found that sulphates, chlorides, and other ions act similarly to fluorine and withdraw a certain amount of iron from solution. The effect of these ions is therefore nullified by adding slight additional amounts of ferric chloride.

The Steiger method,¹⁰ one of the older methods for fluorine, has been modified by both Wichmann¹¹ and Boissevain.¹² In this a peroxidized titanium chloride solution is bleached by fluorine, the amount of fading being proportional to the amount of fluorine present. It is somewhat difficult to detect differences in the fading produced by samples varying by 0.1 p.p.m. fluorine in ordinary Nessler tubes. Undoubtedly the photo-electric colorimeter of Wilcox¹³ used to compare the ferric acetylacetone colors of Armstrong's method would be more sensitive than comparisons in Nessler tubes. Sulphates in excess are known to interfere with this method, and correction is made if the concentration is too high.

Willard and Winters,¹⁴ Thompson and Taylor,¹⁵ and Sanchis¹⁶ use

alizarine red-zirconium nitrate as an indicator in their determination of fluorine.

The Willard and Winters method depends upon removing interfering elements by a preliminary distillation. The fluorine in the distillate is titrated with thorium nitrate, using the above mentioned indicator.

The Sanchis method has been modified from the Thompson and Taylor method for fluorine in sea water and is adaptable to the analysis of fresh waters. Chloride and sulphate effects up to 500 p.p.m. are nullified by the addition of hydrochloric and sulphuric acids.

COMPARISON OF ANALYTICAL RESULTS

Analyses of many waters for fluorine using the Fairchild, Foster, Willard and Winters, and Sanchis methods have been made by the writer and the results compared. These data are presented in Table I. Further evidence is here given that the results of the analysis of waters by the Fairchild method are abnormally high.

On the other hand, results by the Foster, Willard, and Sanchis methods compare very closely with each other, the results obtained by any one of these 3 methods being practically the same.

The results of the analysis of 54 waters by these 4 methods are grouped into 2 classes: (1) waters which are known to be associated with mottled enamel, and (2) those which have been found not to cause mottled enamel. This division is based on tooth examinations made by M. C. Smith.

It may be seen by inspection of Table I that the 33 waters associated with mottled enamel, as analyzed by the Foster, Willard, and Sanchis methods, have a fluorine content varying from 0.7 p.p.m. to 13.2 p.p.m. Twenty-one waters which did not cause mottled enamel had fluorine contents ranging from 0.1 to 0.8 p.p.m.

Severe mottled enamel of the deeply stained and pitted type appear to be associated with waters containing well over 2.0 p.p.m. of fluorine. Waters containing from 1 to 2 p.p.m. were always found associated with a mild to moderate type of this dental defect. That the lower limit of fluorine content in water which causes mottled enamel probably is slightly less than 1 p.p.m. is shown in Eagar, Tucson Brickyard, Florence (private well), San Xavier, Cochise, and Springerville. These waters were found to produce a very mild type of mottled enamel. In Eagar the effect was variable. About 50 per cent of the children in the community had chalky white patches on the teeth, characteristic of mild mottling. Again it may be noted that other waters with a fluorine content of 0.7 to 0.8 p.p.m. did not have a toxic effect upon the teeth, as, for example, the city of Chandler. This community, however, is surrounded by areas in which mottled enamel does occur and in all probability has a fluorine content which is just below the toxic concentration. It is difficult to establish the exact fluorine concentration in a water supply which will damage the teeth of its users. The evidence indicates strongly that any water with a fluorine content of 0.9 p.p.m. (when analyzed by the Foster, Willard, or Sanchis methods) or over is dangerous from the standpoint of probable damage to the teeth. No Arizona water has yet been found containing more than 1 p.p.m. of fluorine which has not been shown to cause mottled enamel.

Dahle,¹⁷ Associate Referee for the A.O.A.C. has compared the Foster, Willard, and Steiger methods by means of analysis of synthetic waters made by 8 chemists in different parts of the country. His synthetic water "A" made up to contain 2.08 p.p.m. of fluorine was found to contain 2.08 p.p.m. by Foster method, 2.27 by the

Willard method, and 1.9 p.p.m. by the modified Steiger method. Little difference in results obtained by these 3 methods was apparent. Therefore it is safe to conclude that the toxic concentration of fluorine is similar when determined by the Foster, Willard, Sanchis, or Steiger methods, and has as its lower limit 1 p.p.m. or slightly less.

REMOVAL OF FLUORINE FROM WATER SUPPLIES

Because certain communities find it impossible to secure waters containing too little fluorine to cause mottled enamel, a practical method of treating the water to remove fluorine must be developed. Many years ago Carnot¹⁸ reported that it was possible to remove fluorine from water by the use of bone. This removal is probably due to the fact that the CO_3 in bone $\text{Ca}_{10}\text{CO}_3(\text{PO}_4)_6$ can be replaced with fluorine. A single trial in our laboratory has been made of this method. When 67.5 mg. of bone was used per liter of water, the original fluorine concentration of 2.5 p.p.m. was reduced to 1.7 p.p.m. The possibilities of this method are under further investigation.

Willis of the Colorado Springs High School¹⁹ has studied the waters in the mountains above Colorado Springs in an attempt to determine the source of fluorine in Colorado Springs water supply. Analyses of water from the same source showed lower concentrations of fluorine during winter than summer, hence the possibility of "freezing out" the fluorine suggested itself.

Through the courtesy of the Arizona Ice and Cold Storage Company in Tucson it was possible to conduct a freezing experiment under commercial conditions. Water originally containing 0.7 p.p.m. fluorine was fortified with a sodium fluoride solution. A concentration of 3.4 p.p.m. resulted. The tank containing the mixture was placed in the

brine to freeze. Agitation was obtained with compressed air. Two cores were removed. The cake of ice was sampled and analyzed for fluorine by the Sanchis method. Results are shown in Table II.

TABLE II
REMOVAL OF FLUORINE BY FREEZING

	Fluorine in p.p.m.
Original Water	0.7
Water and added NaF	3.4
First Core Removed	6.0
Second Core Removed	4.0
Sample No. 1 Outer Portion	0.7
Sample No. 2 Outer Portion	0.4

It is a well known fact that ice freezes almost pure. In this case the impurities were concentrated in the core. It is doubtful whether this method of fluorine removal would be any more practical than distillation.

A verbal report of Dr. Frary of the Aluminum Company of America, at the meeting of the American Chemical Society in Chicago in 1933—that activated aluminum would remove all traces of fluorine from solution—apparently has not yet been published.

Boruff²⁰ has reported the removal of fluorine from water by the use of aluminum sulphate. Water containing 2 to 3 p.p.m. of fluorine required 85 p.p.m. of the anhydrous salt, or 165 of the crystalline, to lower the fluorine concentration to the safe level of 0.5 p.p.m. At \$4.42 per 100 lb. for aluminum sulphate, the cost of treating 1,000,000 gallons of water would be \$60.77. This cost is prohibitive for municipal supplies. If only drinking water were treated, the cost of 6.07 cents per 1,000 gallons for chemicals would be very economical. No reports of the use of this method have been noted. The writer has attempted to corroborate Boruff's results and especially to modify his procedure to render it more practical by securing more complete removal with less aluminum.

In some cases residual aluminum re-

mained in the solution. Under these conditions fluorine results by the Foster method were lower than by the Willard and Winters method, and it is assumed that aluminum sulphate was responsible for this. Further studies are being conducted to discover the cause.

McKee and Johnson²¹ have recently suggested the removal of fluorine by the use of activated carbon after the pH of the water has been reduced below 3.0. Cost of carbon, acid, and lime will not permit the use of this method by a municipality. The practicability of any of the heretofore proposed methods for the removal of fluorine from municipal supplies seems doubtful. When it is realized that only 1 p.p.m. of fluorine in water is necessary to cause mottled enamel, it is not surprising that attempts to remove these small amounts have not met with greater success.

SUMMARY

1. A concentration of 0.8 to 0.9 p.p.m. of fluorine in water has been found to cause mottled enamel if this water is consumed while the children are of a susceptible age.
2. A comparison has been made of 4 methods for the determination of fluorine in water.
3. Experimental work has shown the Foster method to be unsatisfactory when used for the fluorine determination on waters which have been treated with $Al_2(SO_4)_3$ for fluorine removal if considerable aluminum remains in solution.

ACKNOWLEDGMENT—The writer is indebted to Jane Rider in planning and executing part of the experimental work presented here as well as for a criticism of the manuscript, and to W. T. McGeorge and T. F. Buchrer for suggestions and help in designing equipment used.

DISCUSSION

J. M. SANCHIS

Chemist, Bureau of Water Works and Supply, Los Angeles, Calif.

MR. SMITH has summarized effectively the extent of our present knowledge in regard to the various aspects of the problem presented by the occurrence of fluorides in potable waters.

His timely remarks on the importance of the part played by analytical procedures in any attempt to ascertain the toxic level of fluoride in water, based on field observations, cannot be overemphasized. Without a reproducible unit of measure, little progress can be made in the evaluation of data obtained from widely scattered localities.

As pointed out the methods which have been used most generally in recent years can be grouped into two main classes. Those in one class make use of the fact that fluorides interfere with the quantitative estimation of ferric ions, while those in the other class depend on the effect of fluorides upon the color produced when alizarin reacts

with zirconium in a hydrochloric acid solution.

The Foster method is the best known of the procedures in which use is made of the ferric ion reaction. This came at a time when the inconsistency of the results obtained by the then available methods had thrown laboratory findings into a hopeless state of confusion. Its relative superiority over the other methods caused its ready acceptance by those confronted with the need of making fluoride determinations. However, the results obtained by it were not always reliable nor easily duplicated. Boruff and Abbott¹ pointed out a number of theoretical considerations by which they proved the fundamental weakness of the method even in the absence of interfering substances. When to this is added the effect that reducing agents such as hydrogen sulphide have upon ferric ions, the difficulty in which the thiocyanate colors can be matched when using Nessler tubes or the

Duboscq type colorimeter, the errors introduced by the rapid fading of the color, the need of corrections for the interfering effect of certain ions commonly present in water, etc., it is surprising that results comparable to those given by other methods are so often obtained. It is true that the use of photronic cells and the substitution of other indicators, such as acetylacetone, for the thiocyanate have done much to improve the procedure. It is very questionable, however, that these improvements can overcome the fundamental weakness of the ferric ion reaction.

On the other hand, the relative freedom from common interfering substances of the zirconium alizarin methods places them at a decided advantage over the ferric ion procedures. The Willard and Winter distillation method, as modified by Boruff and Abbott¹ is at this time recognized as the most reliable method at our disposal. Except in very unusual waters, equally satisfactory results have been obtained consistently by the direct zirconium alizarin colorimetric procedures. One of the outstanding advantages of these colorimetric methods over those using the ferric ion reaction is the permanency of the colors produced and the ease with which the colors may be compared with the standards when using ordinary Nessler tubes.

In the matter of analytical procedures, we may say that considerable progress has been made. We have now at our disposal several reliable methods and it is only a question of deciding which of these is best adapted to our needs.

The results obtained by these better procedures indicate that fluoride concentrations in excess of 2 p.p.m. are, as a rule, associated with more or less noticeable defects in tooth structure. Between this concentration and 1 p.p.m. the toxic effect produced by a given quantity of fluoride in the water

seems to vary considerably in different localities. This apparent fluctuation in toxicity suggests that other factors may play an important part in the effect which the fluoride present in the water supply exerts upon tooth enamel.

One of these may be the amount of fluoride taken into the system through articles of diet other than water; another is the possible presence in the water or other food products, of ions which in some way prevent the fluorides from exerting their toxic effects.

Some of the recent work done by Smith and Leverton² at the University of Arizona has shown that the total amount of fluoride ingested, irrespective of its source, is one of the controlling factors governing the production of mottled enamel. As we know, fluorides are present in variable amounts in most of our food products. It is interesting to note that milk and certain vegetables have been considered by physiologists as the source from which the body obtains its normal fluoride requirements. Although there are no experimental data available to establish the relationship between the fluoride content of food products and that of the water which helped to produce them, it seems reasonable to believe that a more or less direct relationship exists. If this were the case, it would be logical to expect that in isolated farms or small farming communities, where practically all foodstuffs are produced locally and where the same water is used for all purposes, the fluoride content of the water will be a deciding factor in controlling its potability. On the other hand, in larger communities, where the water and food supplies are drawn from widely scattered areas, the same fluoride content in the water, within reasonable limits, may not be of much significance.

The second factor to be considered, has to do with the well known physiological phenomenon produced by ion

antagonism usually referred to as the balancing function of salts. A number of cases are known in plant and animal metabolism where the toxicity of certain ions is diminished if not altogether neutralized by the presence of some other ion or ions which by themselves may or may not be detrimental. The extent to which this neutralization takes place depends upon the amount of each ion present, there being a certain proportion at which the balancing effect will be greatest. The Smith-Leverton studies previously mentioned have demonstrated the inhibiting action which calcium exerts upon the potential toxicity of fluorides. This interference, whether due to ion antagonism or merely a solubility effect, clearly indicates the possibility that other untried combinations may bring about similar results.

Definite information on these factors would go a long way toward making possible the intelligent appraisal of the potential toxicity of fluoride concentra-

tions within the doubtful range. This information may, in the absence of practical methods for fluoride removal, even suggest the introduction of substances containing fluoride antagonistic ions in the diet as a logical solution of the problem when a better source of water supply cannot be obtained.

Until more definite information on the various factors involved is available, we may, for the sake of safety, look with suspicion upon waters containing fluoride in concentrations greater than 1 p.p.m.

Much has been learned, but there is still a lot to be known. The foundation has been laid and a wide field of research is open to those who, having the time and facilities, welcome the opportunity to be of service to their fellow men.

School Health Studies

DOCTEUR R. H. Hazemann, M^ed^ecⁱn-Inspecteur, de l'Office Public d'Hygiene Sociale, Prefecture de la Seine, of Paris, writes to the Association that the article by Dr. Donald B. Armstrong, in the January 1935 *American Journal of Public Health*, entitled "Report of Special School Health

Studies in New York City," was so interesting that he translated it into French for a medical meeting even before he had official permission for the translation or copyrighted material. The Association is glad to join Dr. Armstrong in approving the translation of this material.

Relation of Action of Chlorine to Bacterial Death*

C. S. MUDGE AND F. R. SMITH

Division of Dairy Industry, University of California, Davis, Calif.

CHLORINE in the form of gas or of its many compounds has found wide use in public health work. It is perhaps the most popular of the numerous germicides—seemingly an effective agent in causing bacterial death.

This bacterial death, however, is a somewhat misunderstood phenomenon, largely because there are no well defined criteria for it. With bacteria any measure of death is negative, a sort of inverse to life, since one must grow the organisms surviving in order to arrive at the number dead. With animals, any of several phenomena can be used as an index of death—for example, rigor mortis and cessation of heart beat. With higher plants there are criteria, somewhat less well defined, that tell when life is gone, but in the case of bacteria, no such tests exist.

Fulmer and Buchanan¹ have used a vital staining technic which they claim is a satisfactory criterion under certain conditions. According to them, "All cells which take up the stain (methylene blue) are dead, that is, they no longer can reproduce." Five words of this quotation tell the story—"they no longer can reproduce." The reproductive phenomenon in some form is always used in studies of bacterial death; and all our concepts of lethal action are

based on the hypothesis that if the bacteria do not reproduce they are dead.

That this basic premise is incorrect has been shown by Rahn and Barnes.² Although these authors used yeast as a test organism, their results are applicable to bacteria. They subjected bottom yeast to the action of 4 lethal agencies: heat, mercuric chloride, ultra-violet light, and X-rays. At definite intervals the survivors in the cultures were enumerated by the plate count (to show reproduction), gas production (to show enzyme action), staining reaction (to show dead tissue), and coagulation. The cells lost first their power of reproduction, then their enzyme activity. Considerably after losing these 2 powers, they took the stain; and later they coagulated. Data in this paper indicate that for a given time the plate count showed but 0.0002 per cent survivors, whereas the fermentation and stain test showed 5 per cent and 39 per cent living, respectively. Rahn and Barnes consider that the coagulation of the cell protoplasm is not the fundamental reaction of cellular death.

This concept is at variance with a considerable body of opinion to the effect that coagulation is important. Heilbrunn³ accepts the latter view and cites many instances of belief in it. Bancroft and Richter⁴ have studied the action of germicides under the ultra-microscope, using various lethal agents upon yeast cells. They report seeing a

* Read at a Joint Session of the California Association of Dairy and Milk Inspectors and the Laboratory Section of the American Public Health Association at the Sixty-third Annual Meeting in Pasadena, Calif., September 6, 1934.

visible coagulation that led them to "understand readily why the cells die." The "death" that they described was, unfortunately, not checked by the usual means. Perhaps the most original part of their work was the direct observation that the coagulation within the cell is reversible. This reversibility they noted; and, if there is any correlation between their coagulation and death, the death process too must be reversible within limits. They further postulate the grossly empirical equation—

Living bacteria + disinfectant = dead bacteria.

Given such an equation, they believe, certain reaction velocities would obtain. Increasing the disinfectant increases the velocity to the right (McClintic).⁵ Increasing the dead bacteria increases the velocity to the left (Lange).⁶ Increasing the living bacteria, however, throws the equation into a "hideous disagreement"—to use their words. It is their idea that the death phenomenon is reversible—a conception not very new in bacteriological literature. A number of authors have reported such findings. Rodewald⁷ placed the organism causing fowl cholera in a 0.1 per cent mercuric chloride solution. After several minutes the cells were removed and washed. Mice inoculated with them were killed. As a control, Rodewald treated a similar quantity of cells in like manner and attempted to grow them. He failed: the cells were "dead." Similar experiments are reported by Liesegang,⁸ Süpfle and Müller,⁹ Müller,¹⁰ and Gegenbauer.¹¹ All these authors treated cells with various germicides, and by subsequent treatment with antidotes were able to cultivate them, whereas the untreated cells showed no evidence of growth.

The experiment of Süpfle and Dengler¹² is exceedingly interesting, since it apparently indicates that the death phenomenon is a function of the medium used to grow the organisms.

Süpfle and Dengler dried anthrax spores upon silk threads, which were then suspended in a steam bath. After various periods of heating, duplicate threads were removed. One was placed in plain broth; the other in broth enriched by sugar and serum. In the richer medium, the spores germinated after exposure to the steam for a longer time—a very significant observation.

Still another argument can be used to indicate the possibility that the death reaction is reversible. Not only Chick,¹³ but Madsen¹⁴ and Nyman, showed that the action of a lethal substance in a bacterial population follows a rather orderly and predictable course: the death rate in such a population depends on the number of cells living at any given time. Expressed mathematically,

$$\frac{d b}{d t} = K b$$

This, on integrating and evaluating the constant of integration, gives

$$K = \frac{1}{t} \ln. \frac{b}{a}$$

In these equations "a" represents the initial number of cells, "b" the number of cells living after time involved, "t" the time, and "K" the rate of death. The second expression is easily recognized as the monomolecular equation so much used by the chemist for the rate of certain reactions. In this case it is an over-all equation reflecting the action of the germicide on the countless individual cells that make up the population. Some contend¹⁵ that the lethal curve does not follow the monomolecular reaction exactly. There is little doubt, however, that the death phenomenon is chemical in nature, and so it must follow chemical laws in other respects and must be reversible or at least must reach an equilibrium somewhat short of actual death.

There is still another possible view regarding the death phenomenon.

Richet,¹⁶ Gegenbauer,¹¹ and later Winslow,¹⁵ and his coworkers¹⁷ have all shown that for most substances, lethal or not, there are concentrations which first stimulate, then inhibit, and later in higher concentrations kill. Gegenbauer postulates zones of life, of dormancy, and of death, but dormancy is not death, though the criterion is likely to be the same—failure to reproduce.

Is it possible in much of the work where "death" has been studied that dormancy alone has been observed and that the cells were indeed alive? If so, most concepts of the action of certain germicides need revision. The work of Leonard¹⁸ apparently leads to the same conclusion. Studying the phenol coefficients of certain compounds, he pointed out that the Hygienic Laboratory makes no claim for this method unless the germicide is closely related to phenol. Those with which he worked were not related. He attempted to determine whether the effect of his compounds was really lethal or merely bacteriostatic—that is, whether he had death or dormancy. To do this he took the 15 minute tubes of the usual test and transferred a loopful of the contents to tubes of fresh broth. In this way the germicide was further diluted. When the transfer was from the phenol tubes there was no growth, whereas the tubes made from his unknown showed growth.

We are especially interested in chlorine compounds, particularly the hypochlorites. These compounds are extensively used in dairy plants and on producing farms. In many instances, particularly on dairy farms, chlorine compounds are the sole means of sterilization. This situation is seemingly justifiable, since the literature is filled with studies made on such compounds. Always the results are reported to be satisfactory. Hypochlorites are supposed to have an exceedingly

high phenol coefficient. Zoller¹⁹ reports 300 for instance; Tilley²⁰ 80 to 90. In the light of Leonard's work, one wonders whether such high phenol coefficients are reliable. Possibly the reaction may be reversible. Furthermore, dormancy or bacteriostasis may have been the pitfall for the unwary in such studies.

We report the results of several experiments on the germicidal action of chlorine compounds. Our procedure was essentially the same as that of many others found in the literature, and the results are in entire accord with theirs. We went just one step farther, however, made observations that to us seem highly significant.

METHODS

For organisms we used milk in which bacteria had grown. This milk had a population well into the millions but contained no clots in which bacteria might be trapped. It was diluted with distilled water in various ratios. The presence of milk in our active mixtures has an excellent precedent in the work of Chick and Martin,²¹ who postulate that the action of lethal agencies on bacteria is best carried out in an environment where bacteria can live. The bacteria in such milk were assumed, furthermore, to represent those forms that the disinfectant must combat in actual practice. Although the flora of our various experiments varied, the constancy of our results left no doubt that the practice was valid. The hypochlorite used was the liquid bleach of commerce, containing about 16 per cent available chlorine. It was strongly alkaline, for there was residual alkali in the container. In order to stop the action of chlorine and thus prevent a bacteriostatic action in the plate, 0.5 c.c. of a sterile 1 per cent solution of sodium thiosulphate was added to each plate which had previously been shown to have no effect on colony counts. Being interested in trends and not in

absolute values, we used only 2 dilutions. Some of the colony counts were exceedingly high. In order to count such crowded plates, we used a dissecting microscope, calibrating the field with a given magnification in terms of the petri dish area. Whenever resort was made to the microscope, 8 to 10 fields were counted, and averaged.

We cannot submit all our experiments for lack of space. Our results, furthermore, do not lend themselves to the process of averaging, dangerous in itself; so we submit a protocol (Table I). The higher numbers of colonies in

sulphate is present than where it is not. It is strange that more workers have not used thiosulphate to offset the effect of the germicide itself. The most interesting observation in our work is splendidly exemplified in the protocol: the 1-10 dilution made in addition to the usual direct plate is always the higher of the two. One may reasonably assume that if the plate made direct from the active mixture shows 5,000 colonies, then the 1-10 dilution should have but 500, but instead of 500, there are 28,000. We found this "jump up" throughout our work, re-

TABLE I

PROTOCOL OF EXPERIMENTS SHOWING THE EFFECT OF CHLORINE ON BACTERIA

Initial bacterial count: 100,000,000

Ratio of milk to water: 1-10

Time of Action of Chlorine, Minutes	Plate Dilution	Concentration of Chlorine p.p.m.	Liquid Bleach	
			No Thiosulphate	With Thiosulphate
3	1-1	50	5,000	294,000
3	1-10	50	280,000	224,000
5	1-1	50	33,000	56,000
5	1-10	50	640,000	160,000
10	1-1	50	48,000	67,000
10	1-10	50	196,000	640,000
3	1-1	100	28,000	5,600
3	1-10	100	600,000	144,000
5	1-1	100	33,000	33,000
5	1-10	100	960,000	960,000
10	1-1	100	33,000	28,000
10	1-10	100	1,312,000	224,000
3	1-1	200	210	2,000
3	1-10	200	4,300	5,800
5	1-1	200	324	2,100
5	1-10	200	1,000	5,800
10	1-1	200	762	3,240
10	1-10	200	3,600	5,040

plates with thiosulphate are to be noted. Particularly important is the fact that the 1-10 dilution gives a higher count than the direct plate (1-1).

A very satisfactory reduction in bacteria was caused by the action of the hypochlorite—a result in accord with the usual findings (Table I). The protocol also shows, as might be expected, that in most cases the counts are higher in the plate where the thio-

gardless of the amount of milk present, the strength of the chlorine, the time of action, or the presence of thiosulphate.

Diligent study has been made of the "jump up," which is doubtless a phenomenon similar to that described by Leonard. The next experiment follows naturally the conclusions of the one above. A mixture of bacteria with water was taken. It was our plan to plate this mixture both before and after

the action of chlorine. To check the plate count which—according to Rahn and Barnes—gives the first evidence of death, we also ran serial dilutions on the same mixture at the time the plates were made. We expected close agreement between the plate and the dilution tube before the action of chlorine. For instance, a mixture showing a colony count of 1,000,000 would also show growth in tubes out to at least the 10^{-6} dilution. After the action of chlorine we thought that there might be a discrepancy between the plate and the tube. The 1,000,000 bacteria (of the previous example) might be reduced to 1,000, as evidenced by the plate count. The serial dilution tubes should not show growth in dilutions greater than 10^{-3} . The experiment indicates the correctness of our reasoning. There is close agreement between the plate and tube before the action of chlorine (Table II, columns 2 and 3), but after no such agreement is noted (columns 4 and 5). The plate count shows the expected decrease up to 99 per cent. The serial dilution tubes, however, show growth in as great dilutions after the

action of chlorine as before. There is, therefore, virtually no reduction as measured by this method (column 7).

By one method there is evidence of death; by the other, no such evidence. Both cannot be right.

Admittedly, errors are inherent in the dilution technic. However, a dilution procedure is also an integral part of the plate method, so that the inherent errors are more or less common in both cases. Furthermore, we obtained these results with such regularity that there is little doubt as to their essential truth. In the light of all the evidence cited, together with that which we submit, there are apparently few tests that can be relied upon where bacterial death is concerned.

SUMMARY

The literature shows that—

1. Bacterial death is to a certain extent reversible.
2. There are "zones" of life dormancy and death.
3. The action of some germicides result in dormancy and not death;
4. The measure of death is sometimes a function of the media used to grow the survivors.

TABLE II

COMPARISON OF THE PLATE COUNT WITH THE SERIAL DILUTION BEFORE AND AFTER THE ADDITION OF HYPOCHLORITE

Time of Action of Chlorine in Minutes	Before the Addition of Chlorine				After the Addition of Chlorine		
	Numbers of Bacteria as Indicated by Colony Count	Numbers of Bacteria as Indicated by Serial Tubes	Numbers of Bacteria as Indicated by Colony Count	Numbers of Bacteria as Indicated by Serial Tubes	Percent Reduction as Indicated by Colony Count	Reduction Indicated by Serial Tubes

	5	1.2×10^5	1×10^6	3.1×10^4	1×10^6	99.0	0
	10	1.9×10^5	1×10^6	1.9×10^4	1×10^5	99.0	0
5	3	2.3×10^7	1×10^6	1.2×10^6	1×10^6	95.0	0
	5	2.5×10^7	1×10^7	7.8×10^5	1×10^5	95.0	+
	10	2.1×10^7	1×10^6	4.1×10^5	1×10^5	95.0	+

Our investigations show that—

1. The colony counts increase as the dilutions increase.
2. There is no accord between colony counts and serial dilutions.
3. Growth was observed in as high serial dilutions after chlorination as before.

Organized Medical Care

IT would appear that if medical care is provided on some organized basis, it should be possible to define the two fields so that there will be a complete curative and preventive service without any overlapping. In order to attain the fullest coördination, it would be desirable to have the provincial department of health responsible for the administration of all medical services, including hospitals, for which the province assumes responsibility. . . . The public health authority should have in mind that administrative responsibility does not mean a dictatorship. In England, health insurance is administered centrally by the Ministry of Health, which also appoints the regional officers, who act as medical referees and inspectors. The Ministry, in the exercise of its administrative powers, turns to the British Medical Association for advice and assistance. The strength of health insurance in England is largely

due to placing control for the professional side of the medical benefit with the medical profession. This is something for public health authorities to keep in mind, if they are ever called upon to administer some form of organized medical care.

A fair criticism of health insurance is that it has not been preventive in practice and but little in outlook. It is not enough to render lip service to the idea of the practice of preventive medicine by the general practitioner, and then to disregard him in planning public health services. Under whatever name organized medical care is provided, it should make possible the systematic practice of preventive medicine, including periodic health examinations, by the general practitioner. . . .—The Relationship of Public Health to Medical Care, Grant Fleming, M.D., McGill University, Montreal. *Canad. Pub. Health J.*, Oct., 1934, p. 465.

Training Sanitary Inspectors*

WALTER S. MANGOLD, F.A.P.H.A.

*Sanitary Instructor, Los Angeles County Health Department,
Los Angeles, Calif.*

AN interesting experience in what a trained layman can accomplish is related by Dr. W. G. Smillie, Professor of Public Health Administration, Harvard School of Medicine:

Some years ago in Alabama an active campaign was being waged for the control of tick fever in cattle. Federal authorities aided by other specialists met with considerable opposition in certain areas. This took the form of having dipping vats dynamited and being shot at from ambush. As officials were discussing their predicament one evening, they were called on by a townsman, one John Boggan, who offered to help them. He suggested that he be taught the control methods and other facts about this disease, and then he would be willing to put these measures into practice. At the end of a short schooling, Mr. Boggan, who was amply supplied with native intelligence, went into the troublesome districts and successfully instituted the tick eradication campaign. This incident is applicable to the work of the sanitary inspector.

In the city of Washington, in 1922, a group of public health officials and educators held a conference to consider means of bettering the public service. Among their conclusions were the statements that the future of public health

did not depend so much on new scientific data or a well informed public as it did on the matter of personnel. Dr. C.-E. A. Winslow, Yale School of Medicine, stated at that time, in reference to the specialists whose viewpoint and training are primarily concerned with the nonliving environment of man:

We may naturally place in this general group one of the most important and neglected figures in the whole public health campaign, the inspector in the control of sanitary conditions and in supervision of food supplies. There is urgent need for a large group of men or women who do not necessarily require a college education but who do need substantial training of an elementary kind for which as yet no provision whatever has been made in the United States.

Edna Trull corroborates these statements in a study of this position. She finds that the statement "the health inspector is one of the most influential agents of the city in promoting and safeguarding the health of its citizens" cannot be questioned when the scope and importance of his duties are taken into consideration. "When the amount of personal responsibility, initiative and good judgment required of an inspector are taken into account, it is apparent that his training, ability, and status in the administrative personnel are entitled to consideration similar to that given to the other protective forces of the community."

The duties of the sanitary inspector have increased rapidly from the begin-

* Read at a Joint Session of the California Association of Sanitarians and the Public Health Engineering Section of the American Public Health Association at the Sixty-third Annual Meeting in Pasadena, Calif., September 4, 1934.

ning of this century to the present time. Formerly, the inspector acted as quarantine officer and enforced general nuisance laws, but with the advancement of the sanitary sciences, new methods for the detection, diagnosis, and control of communicable diseases were adopted. Higher standards of community sanitation also prevail over those of 30 years ago. All this has entailed new duties of a semi-professional nature which require, at the very least, a casual acquaintance with many sciences and an intimate knowledge of enforcement procedure. The inspector's daily routine now brings him into the field of medicine, sanitary engineering, bacteriology, chemistry, veterinary science, law, entomology, architecture, trade practices, and business management. To expect any ordinary individual to pick up the necessary information in a haphazard manner and efficiently to execute his mandatory duties is beyond reason. The only equitable solution to such a problem is to institute a well planned course of training which embodies the fundamental principles of environmental sanitation and standardized methods of procedure.

The health officer or specialist need not fear the increased knowledge and efficiency of the inspector for, rather than encroach upon the expert's field, the inspector relieves the technician of many of his routine duties. He thereby becomes a reliable worker supplementing, not obstructing, the work of his superior officers. Due to his broader understanding of the general affairs of the health department, the inspector through his extended field of contacts, becomes a valuable aid to the health officer in promoting public relations and assisting in special feature programs.

The need of training is felt not only in this country but in others where the control of certain communicable diseases is imperative or desired. A recent book on public health in the Union of

Soviet Socialistic Republics contains the statement that, although the number of cases of dysentery, typhoid fever, typhus and relapsing fever is abnormally high, "there is no complete provision, as yet, for the special training of sanitary officers, or for insisting on their possessing a satisfactory diploma before they undertake public health supervision and control."

The only country which has satisfactorily dealt with this problem is England, where, as early as 1877, the Royal Sanitary Institute organized courses of training for sanitary inspectors. It is practically impossible for an individual to receive appointment as sanitary inspector without holding a certificate of proficiency from this non-official organization.

In the United States, many attempts have been made to establish this type of training. The most outstanding measures are those in effect in New Jersey, Tennessee, and Los Angeles County. In the first state, the legislature in 1903 passed laws for the licensing of sanitary inspectors; amendments in 1920 set up 3 classes of inspectors. These regulations have been supplemented by summer short courses at Rutgers University.

The Tennessee State Department of Health coöperates with the University of Tennessee in training inspectors for a 3 months' full-time period. These students are trained specifically for positions with the county health units. The regulations of the state department establish the following requirements for sanitary inspectors in county health departments: certificate of good health, necessary personal and moral qualifications to carry on their work adequately, high school graduate, 3 months' special instruction in sanitation or its equivalent, and at the time of initial appointment must be not less than 25 years of age, nor more than 35. This standard is probably the highest for any health department in this country.

In the Los Angeles County Health Department, a School of Sanitary Instruction was organized in 1930 and a full-time position of Sanitary Instructor created. This school has successfully completed 12 courses of instruction ranging from the fundamentals of sanitation to classes in teacher training.

There has been a group of inspectors working under the name of the California Association of Sanitarians who have twice presented to the state legislature a bill for registering sanitary inspectors. This measure would allow all inspectors to register during the first year after enactment without examination and, thereafter, a course of training from a certified school followed by an examination would be required before a registration certificate would be issued. The bill will be presented again to the next session of legislature.

The School of Government, University of Southern California, during the last 4 years has given certificates for certain types of governmental services. It is now considering the establishment of courses leading to a Certificate in Public Health Sanitation. To this end a graduate student, Grace Loye, is making an analysis of the duties of the sanitary inspector in Southern California, and also the required knowledge to execute these duties. Plans will be submitted to the American Public Health Association for correction and approval.

At this time I wish to submit the following plan which is based on the opinions of public health leaders and educators in this country:

1. That the American Public Health Association establish a Board for Certification of Sanitary Inspectors with a full-time executive secretary. Such board shall promulgate rules, procedure for certification, standards, and fees.

2. The Board shall appoint State Boards of Examiners to conduct examinations and certify applicants to the Association.

3. The Board shall set up a standard course of instruction for schools to teach. After 2 years, only those who have taken such a course will be eligible for examination.

4. The U. S. Public Health Service and Rockefeller Foundation should be encouraged to coöperate with this plan in those counties where grants are given for public health work.

A simple course requiring 168 hours of class and 132 hours of field work could be organized so that it may be given at a full-time school, night extension classes, or by a correspondence course supplemented by full-time attendance at a coöperating health department. Consideration should also be given to printing a manual of standardized procedure. Although universities ought to give this training, the courses should not be overloaded with university subjects but should rather apply to actual field conditions.

This plan agrees with the objectives of the Committee on Training and Personnel as published in the *American Public Health Association Year Book, 1932-1933*. The program of the committee proposed the following:

1. The definition of different types of public health workers

2. Registration of those workers who are now in service

3. The setting up of definite standards under which individuals may qualify for registration in the future

4. The development of a campaign of popular education for better tenure, adequate salaries, and the appointment of trained workers in the future

5. The development of suitable licensure legislation to necessitate the appointment of trained individuals

In fact, the proposed bill of the California Association of Sanitarians and the proposed certificate course of the University of Southern California both fit into the objectives of this committee.

The training and certification of sanitary inspectors should be given serious consideration at this time before public health departments return to their normal budgets. Such training will give the inspector an opportunity to give better service and entitle this position to a justifiable increase in salary.

General view of the mouth of the Minneapolis-St. Paul sewer. This sewer is to be 24 miles long and will be located about 250 feet under the city. In the background are the historic Indian mounds under which the sewer will be tunneled. The car in the foreground is being loaded with concrete from the mixer. The Minneapolis-St. Paul Sewer District received an allotment of \$16,095,000 from the Public Works Administration for this project which will take about 3 years to complete.

Response of the Peritoneal Tissue to Dusts Introduced as Foreign Bodies*

R. R. SAYERS, M.D., F.A.P.H.A., J. W. MILLER, AND W. P. YANT

Surgeon, U. S. Public Health Service, Washington, D. C., Acting Assistant Surgeon, U. S. Public Health Service, Washington, D. C.; and Superintendent, U. S. Bureau of Mines Experiment Station, Pittsburgh, Pa.

IN recent years much interest has been shown in the response of body tissues to various dusts. The action of inhaled dusts has been studied extensively by Gardner, Mavrogordato, Gye, and others. Gye and Kettle,^{1, 2} have studied the response to dusts injected intratracheally and subcutaneously. Pollicard^{3, 4} has used the cornea and conjunctiva as the sites of study in his experiments. In 1924 experiments were begun at the Pittsburgh station of the U. S. Bureau of Mines⁵ to determine the action and fate of various dusts when injected into the peritoneal cavity of guinea pigs. The conclusions reached at that time were that live animal tissue in all parts of the body tends to react in essentially the same manner to foreign bodies, and that fibrous tissue is formed in the peritoneal cavity by quartz and is not formed by limestone or coal.

Owing to the length of time required to obtain a reaction from dust by inhalation methods and the desirability of determining the harmfulness of a dust in a relatively short time, the peritoneal cavity was chosen for the site of study.

This area is relatively circumscribed, exact quantities of dust can be easily and accurately injected, and the sterility of the material introduced can be preserved. The reaction produced by the dust in the peritoneum is essentially the same as that produced in the lungs. Identical reactions were found in each animal injected with the same material, under the same conditions and examined at the same interval after injection. The gross appearance of the dust nodules was sufficiently differentiated to afford a means of classifying the physiological response to the dusts.

Any dust, when first introduced into the peritoneal cavity, produced a foreign body reaction of varying degrees of severity. This injury subsided in from 1 to 3 weeks. The dust formed nodules of different sizes and shapes. The subsequent behavior of these nodules determined the type of reaction.

In the series reported here, there were 3 distinct types of reaction; an absorption, a proliferative, and an inert reaction. The absorption reaction consisted in the gradual disappearance of the dust from the tissues without the formation of scar tissue. In the proliferative reaction the nodules formed by the dust due to cellular proliferation became progressively larger up to a certain limit, after

* Read before the Industrial Hygiene Section of the American Public Health Association at the Sixty-third Annual Meeting in Pasadena, Calif., September 4, 1934.

which they became fibrosed. In the inert type of reaction the amount of dust found in the peritoneal cavity at the end of 360 days was approximately the same as that noted in 7 days. The nodules, however, changed in shape, became more flattened, and often showed considerable dispersion of dust particles into the surrounding peritoneum.

In preparing the dusts for injection it was desirable that the particle size of each in the series conform as closely as possible to that of the others. In one series of tests, particles that passed through a 325 mesh standard sieve were used. These were less than 43 microns maximum size. In another series, the material was elutriated in a Roller type air separator.⁶ By this method less than 5 μ maximum size were obtained for all of the dusts, with the exception of soapstone, for which the maximum was 8 μ . The median particle size obtained by air separation varied from 0.75 to 1.7 μ (soapstone 3.5 μ). Such small variations in particle size appeared to be of no importance in comparing the physiological responses produced. The air separated particles closely approximate in size those inhaled under industrial conditions.⁷ While the smaller particles were preferable because of their greater assimilation by the cells and the type of reaction was apparent earlier, the 325 mesh material gave the same gross reactions, and material this size is easily obtained without the necessity of expensive apparatus.

A 10 per cent suspension of the dust (previously sterilized in a hot air oven for 1 hour at 150° C.) in sterile physiological saline solution was prepared. Two c.c. of this suspension, equivalent to 0.2 gm. of dust, was injected intraperitoneally into each guinea pig under aseptic conditions. The animals injected with the air separated material were killed and examined 7, 14, 30, 56, 90, 180, and 360 days after injection, and those treated with the 325 mesh

material were examined in 7, 14, 30, 56, and 112 days after injection.

With the exception of bituminous coal, the greater part of each of the dusts in this series was found in the peritoneum of the anterior abdominal wall, the most dependent portion of the peritoneal cavity. The site of the next largest collection was the omentum. Small nodules and dispersed collections of dust particles were also found in the inguinal canals, on the mesentery, liver, intestines, testes or uterus and diaphragm. A small amount of dust was occasionally found on the posterior abdominal wall. In the case of bituminous coal, the greater portion was found in the omentum and mesentery, while a relatively small part was present on the anterior abdominal wall. For comparison in describing the reaction, the nodules on the anterior abdominal wall were used.

PERITONEAL RESPONSE TO THE VARIOUS DUSTS

Calcite, limestone, precipitated calcium carbonate, gypsum, and Portland cement, after being injected into the peritoneal cavity, formed irregular, more or less discrete nodules. In the earlier stages, some congestion and edema was noted about the edges of the nodules. This irritation was relatively slight in all of these dusts except cement, where it was quite severe, due possibly to the chemical qualities of the dust. The initial stage of foreign body irritation had subsided before the end of 30 days after injection. The nodules became progressively smaller as the interval between injection and examination increased; and the decrease in size was accompanied by the production of a fine brown pigment, which appeared at the edges and on the surfaces of the nodules. Gypsum alone of these dusts did not cause the formation of the pigment. The original dust eventually disappeared leaving only brown pigment

particles at the sites of the nodules. Later the pigment likewise decreased in quantity, and in some animals disappeared entirely without the formation of scar tissue. This response, consisting of the disappearance or dissolution of the dust from the tissues has been designated, for the sake of description, as one of absorption.

Quartz and chert, after an initial stage of foreign body irritation similar to that noted in the previous group of dusts, produced nodules which became progressively larger in size. These nodules showed a tendency to fuse together. They presented the gross and microscopic appearance of cellular proliferation. The increase in size continued to progress up to 90 days after injection, after which it remained constant. The nodules then became more indurated and fibrosed. At the end of 360 days fibrosis was well marked. This type of reaction has been called one of proliferation. The chert used was highly siliceous.

Soapstone, carborundum, jewelers' rouge (hematite), anthracite coal, bituminous coal and precipitator ash produced the same type of foreign body reaction in the first 2 weeks as was noted with the other dusts. The early fixation reaction was not severe and subsided quite rapidly. The nodules, at first raised and rounded, became flattened and spreading with irregular edges. Numerous fine isolated particles were noted in the peritoneum adjacent to the nodules. Collections of dust particles were found at various other points in the peritoneum. The amount of dust found in the peritoneal cavity 360 days after injection was approximately the same as that noted in 7 days after injection. The injected dust was neither absorbed nor did it initiate a cellular proliferation. The only change noted was that of the distribution of the dust in the peritoneum. This type of reaction has been classed as one of inertness.

SUMMARY

The tissue of the peritoneal cavity responds actively to a dust introduced as a foreign body, the response being of such a character that it may be used as a basis for the classification of industrial dusts with reference to their pneumoconiosis producing properties. This response falls into 3 groups; absorption, proliferation, and inertness. While the animals were kept on test for as long as 360 days, the response was sufficiently well marked in 90 days to determine the type of reaction, and often, conclusions could be reached in 30 days, particularly if the reaction was one of absorption or proliferation. The reaction produced by each dust was constant and uniform in all animals injected with that dust. It appears that this response of the peritoneal tissue to various dusts can be used to indicate the possible harmfulness of an industrial dust.

CHEMICAL AND PETROGRAPHIC ANALYSES OF THE DUSTS

Calcite—Pure Iceland spar. Chemical analysis showed calcium carbonate, 99.8 and silica 0.1 per cent. Petrographic examination showed a high purity calcite. Median size of the particles, 1.4 μ .

Limestone—A high grade Pennsylvania limestone. Chemical analysis: calcium oxide, 54.4 per cent; magnesium oxide, 0.4; iron and aluminum oxides, 0.4; and silica, 1.5 per cent. Petrographic examination showed granular, irregularly rounded calcite. Median size of particles, 1.45 μ .

Precipitated calcium carbonate—A chemical by-product. Chemical analysis: calcium carbonate, 87.9; magnesium carbonate, 10.0; magnesium oxide, 0.1; iron and aluminum oxides, 0.6, and silica, 0.4 per cent. Median size of particles, 1.28 μ .

Gypsum—The uncalcined, natural mineral. Silica, 1.3 per cent. Petro-

graphic examination showed approximately 30 per cent as calcite in the form of rounded granules and irregular rhomboidal crystals and approximately 70 per cent as fragmented particles of gypsum. Median size of particles, 1.3 μ .

Portland cement—Chemical analysis: calcium oxide, 74.4; magnesium oxide, 2.8; silica, 21.1 per cent. Petrographic examination showed normal Portland cement. The particles were sharp and angular. Median size of particles, 1.5 μ .

Quartz—Two specimens were used. One was ground rock crystal of high purity. Chemical analysis showed 99.4 per cent of silica. Petrographic examination showed clear, crystalline normal quartz. Median size of particles, 1.7 μ . The other specimen was finely ground Pennsylvania quartz, commonly known as flint. Chemical analysis showed 99.1 per cent silica. Petrographic examination showed normal quartz of high purity. Median size of particles, 1.6 μ .

Chert—A highly siliceous chert. The waste product from the concentration of lead and zinc ores. Chemical analysis showed 76.1 per cent silica. Petrographic examination showed quartz and chert, stained with limonite, predominating. About 25 per cent of the silica was normal angular quartz fragments. Median size of the particles, 1.22 μ .

Soapstone—Chemical analysis: total silica, 49.9; calcium oxide, 1.7; magnesium oxide, 26.2 per cent. Petrographic examination showed about 30 per cent as tremolite, about 65 per cent as talc and about 5 per cent as dolomite. Median size of particles, 3.5 μ .

Carborundum—Pure manufactured silicon carbide. Petrographic examination showed no impurities. Median size of particles, 1.15 μ .

Jewellers' rouge—Pure ferric oxide in

a finely divided state. Chemical analysis: ferric oxide, 98.3; silica, 1.5 per cent. Petrographic examination showed a high purity hematite as fine uniform particles. Median size of particles, 0.95 μ .

Anthracite coal—Two specimens of Pennsylvania anthracite were used. The chemical analyses were approximately the same. Petrographic examinations showed about 95 per cent as coal and about 5 per cent as inorganic material. Of the latter, about 60 per cent appeared as quartz and about 40 per cent as calcite, siderite and rutile. Median size of particles, 0.75 and 1.11 μ .

Bituminous coal—Two samples of Pennsylvania bituminous coal were used. Chemical analysis showed one to have 8.5 per cent ash of which 0.8 per cent was silica, and the other to have 8.0 per cent ash of which 3.5 per cent was silica. The median sizes of the particles were 1.15 and 1.19 μ .

Precipitator ash—Collected from stacks by electrical precipitation. Chemical analysis showed 44.7 per cent silica. Petrographic examination showed predominately perfectly spherical fused glass, rounded semifused masses made up of crystallites, some quartz fragments, calcite and coal. Median size of particles, 1.43 μ .

ACKNOWLEDGMENT

Special acknowledgment is made to the Metropolitan Life Insurance Company, which defrayed part of the expenses incurred in the study. Acknowledgment is also made to the kindness of W. A. Selvig and Dr. A. Gabriel of the U. S. Bureau of Mines for the chemical and petrographic examinations of the dusts used in these experiments.

Immunize Now

DIPHTHERIA immunization has been chosen by the May Day Committee of the State and Provincial Health Authorities of North America as the May Day-Child Health Day project for 1935. It was chosen because there has been practically no reduction since 1930 in the number of deaths from diphtheria throughout the United States. Some states have accomplished a marked reduction in the number of deaths, hence it follows that others have a proportionate increase, indicating that the proven method of prevention has not been satisfactorily applied. . . .

Believing that immunization should be the work of the private physicians, and in order to obtain the coöperation of physicians in this work, we offered the suggestion to each state health officer in the United States that he send a communication to each physician in his state urging:

That he remind his patients who have children under school age of the need for immunization

That he ask his patients to bring their children to be immunized

That he make it a routine of his practice

in the future to immunize, during the first year of life, all babies under his care.

Even with certain states nearing the goal of No Deaths from Diphtheria, the Health Officers who have been heard from have responded enthusiastically to this suggestion. Officers of the U. S. Children's Bureau, the U. S. Public Health Service, the American Academy of Pediatrics, and the American Pediatric Society, promised that those organizations will coöperate.

The objective of the plan is to immunize all children between the ages of 6 months and 6 years, and to maintain this as a continuing service. Concerted action by state departments of health, the medical profession, and parents should make the accomplishment of this objective possible. Our task is to assist in getting information on the need for immunization to parents in all communities and to urge them to act without delay. . . .

Since the entire plan is based upon the coöperation of departments of public health and the medical profession, *both should be consulted* in any community plans for diphtheria immunization.—*A.C.H.A. News Release.*

Occupational Hazards in the Agricultural Industries*

ROBERT T. LEGGE, PH.G., M.D.

Professor of Hygiene, University of California, Berkeley, Calif.

BEFORE the modern age of motorization, power, electricity, and the use of chemical products, such as insecticides and other poisons, the farmer, in his rural out-of-doors occupation, enjoyed the reputation of holding first place in longevity tables, but a recent census report on morbidity statistics, shows a 20 per cent reduction in urban infectious diseases, whereas in the rural communities the decrease is only 6 per cent. This is due to better medical care and public health program in our cities, and also to the fact that diseases such as malaria, hookworm, dysentery and diarrhea are more prevalent in the country. On the other hand, we find the farmers' daughters have about one-half the incidence of tuberculosis as the young women of the same age group working in the industries in the city.

Agriculture has developed many specialties, such as cattle and stock raising, dairying, horticulture, floriculture, truck gardening, cotton, forage and grain farming. As new mechanical processes were invented and the chemical and biological sciences developed, agriculture became an industry and farming was no longer a trade, but a profession.

It is rather difficult to secure mor-

bidity reports from rural districts, and to determine the exact number of non-fatal accidents, since they are not reported to health officers as is customary in large cities.

OCCUPATIONAL ACCIDENTS

In most states, the farmer does not come under the Workmen's Compensation Act; and in those states which form the exception, only if the accident or death is the result of machinery or occupational disease. The number of accidental deaths among farmers and farm laborers in California for 1933, reported by the Industrial Accident Commission, was 67 out of a total of 401 claimed as a result of all causes chargeable to industry. The 67 deaths resulted from accidents arising from the use of farm machinery, such as tractors and motors, falls, fire, electric shock, run-aways, and kicking and horning by animals. Only 2 other vocations had higher mortality rates. Seventy-nine hundred and fourteen non-fatal accidents were reported, placing agriculture first in the 35 tabulated industrial divisions listed.

The toll of accidental deaths in agriculture is annually increasing due to the introduction of motor driven farm machinery and electric power. In some agricultural states, Nebraska as an example, in 1929 the accidental deaths on the farm were twice as numerous as those in the manufacturing industries.

* Read before the Industrial Hygiene Section of the American Public Health Association at the Sixty-third Annual Meeting in Pasadena, Calif., September 5, 1934.

In Kansas during the same year, of the 159 agricultural deaths, 22 were due to non-auto vehicular accidents—18 from farm wagons and 4 from hay racks; 25 were due to animals—kicks and falls from horses, gorings and injuries by cattle. Electricity took a toll of 37 victims, 8 of these being struck by lightning. Of 83 drownings, 5 occurred in stock tanks. Forty-nine persons were killed by special farm machinery, such as balers, thrashers, gang plows, and harvesters. In Nebraska and Kansas, 145 fatalities were caused by tractors, this important modern power machine taking first place as a cause of death and occupational accidents. Carbon monoxide asphyxiation from gas engine exhausts, falls from trees, etc., played a part in the fatal accidents.

The average age at death for the agricultural worker is 56.3 years, according to the U. S. Bureau of the Census life tables published in 1910.

In 1932 there were 15,000 accidental deaths among those engaged in gainful employment. The National Safety Council classified 3,500 of these as belonging to the agricultural occupations. In the same year, the Kansas State Board of Health listed 195 industrial deaths, 105 of these occurring in agricultural pursuits. The most common cause of fatality in connection with agricultural work was farm machinery, followed in order by injuries by animals, falls, lightning, and excessive heat.

Official reports for Canada for 1932 give the number of fatal industrial accidents as 961, of which 154 were chargeable to agriculture.

In England, according to the records of the Registrar General for 1900–1902, the death rate for occupied males in agriculture as compared with all males in the age group between 15 and 65 was 13.61 to 16.23.

According to the United States Census of 1930, the number of gainfully occupied males from 15 to 64

years of age was 14,013,367, with deaths from all causes 121,951 or a death rate of 8.70 per 1,000. The agricultural workers numbered 2,008,330, which included farm owners, managers, and laborers; and deaths from all causes were 13,479, or 6.71 per 1,000. The accidental death rate of this group of agricultural worker was 15.8 per 100,000 from all causes.

OCCUPATIONAL DISEASES AS A RESULT OF PLOWING AND HARVESTING

In our southern states, hookworm is common among the farmers and their families. Especially is this disease more prevalent where sanitation is lacking and field workers go barefooted. In the tropical rice, tea, and rubber plantations, it has been estimated that 60 to 80 per cent of the coolie farm laborers harbor this parasite.

One of the well known irritants to the unbroken skin is lime dust, prevalent during the period in which the tillers prepare the soil, spreading lime on the fields. Manure from herbivorous animals is used especially for the fertilization of the field and truck gardening. It is believed that horse manure contains many tetanus organisms. The danger of tetanus is greater in injuries among tillers of the soil and barnyard workers than among city workers, since the automobile has replaced the horse drawn vehicles.

The so-called tropical skin disease, the classical disease due to prolonged exposure to heat and light of the sun's rays, has long been known to agriculturists on the prairies of Kansas as "farmer's skin." In Kansas in 1932, 6 deaths were reported as due to excessive heat.

Pollens and irritating dusts from plants cause considerable morbidity among field laborers. I recall one farmer who on account of hay fever was obliged to vacate his hay ranch annually to go to the seashore when the red top

and timothy were being harvested. In California, annually, tons of hops are produced for export and home consumption; the hops produce fine hair-like processes, which produce the so-called hop pickers' ophthalmia.

OCCUPATIONAL DISEASES AMONG GRAIN AND FORAGE RANCHERS, TRUCK GARDENERS AND NURSERY MEN

In the harvesting and storing of grain, hay, and different forages, certain bronchial and dermatological lesions are likely to develop especially when these products are infected with mites and moulds. The dusts produced may be contaminated with spores of certain fungi; for example, the *Aspergillus* and *Penicillium*, which when inhaled produce asthma and a bronchial infection. Patients with early cases have coughs and muco-purulent expectoration but no fever, while advanced patients present all the symptoms of tuberculosis. Two such cases were treated among college boys, sons of farmers, who contracted the infection during the summer vacation. One was entirely cured by administering iodides and a vaccine. The sputum shows conidia and spores of the fungi with fragments of mycelium.

Sporotrichosis is another fungus disease due to one of the *Sporotrichum* species, which it is said, is saprophytic on certain vegetables, such as lettuce, and found on the barberry (*Berberis thumbergii*). Truck gardeners and nursery men may become infected. The lesions produced are indurated, chancre-like swellings of the skin which may ulcerate and involve the lymphatics. The administration of iodides internally with tincture of iodine locally is reputed as specific. According to L. Schwartz, U. S. Public Health Service, dermatitis due to plant poisoning among gardeners and florists was due to this cause.

Certain grain regions are infected by a mite; the *Pediculoides ventricosus*

causes the farmers handling the grain and straw to have a skin disease characterized by intense itching with an urticarial eruption. To the late Dr. J. F. Schamberger, of Philadelphia, belongs the priority in describing this affliction in this country (1910). The writer of this paper published in 1921 an article on what was called in California "Packers' Itch." Infected straw, used at a tile works and an electrical fixture factory, caused the itch. The mites were found on the straw. Fumigation and exposure of the straw to sunlight destroys the mite.

Floriculturists frequently suffer from dermatitis venenata, usually on the hands and arms, from coming in contact with certain plants. It is estimated that about 60 plants possess this irritating effect, notably primulas, sumac, pyrethrum, and chrysanthemums. The worst offender affecting farmers and lumbermen of the Coast Range Mountains of California is the *Rhus diversiloba* (poison oak). This plant produces an itching erythema which often develops into vesicles and bullae with marked swelling. The active principle is due to lobinol, isolated by McNair in 1921. The handlers of these plants constitute a considerable percentage of cases of occupational dermatitis: in New York state out of 449 cases, 14 per cent, and in Ohio out of 4,600 cases, over a 5 year period, 2 per cent.

OCCUPATIONAL DISEASES DUE TO PARA- SITES AND INSECTS

Examples of certain infections resulting from contact with animals and plants have been given in this paper. For elaboration, consult a work on medical entomology and note the various vectors, parasites, moulds, and scales that are responsible for infecting agricultural workers. The itch mites (*Sarcoptes*), the wood ticks (*Ixodes ricinus*), the various ringworms (*Trichophyton*), and scald head (*Favus*),

are examples of etiological factors. There is also a common dermatomycosis that attacks stockmen, caused by the *Ectothrix trichophyton* which produces a ringworm, a common infection of horses and cattle.

Certain meals used for feeding dairy stock contain a mite known as the *Tyroglyphus* which produces an itch of the hands. This is the so-called "Grocers' Itch." Linseed meal or meal cake also causes an eczematous eruption on the hands of the dairyman.

In California during the past few years, several cases among farmers have been reported of "bites" by the Black Widow spider (*Lactrodectes mactans*). This highly poisonous insect inhabits old out-buildings, particularly privies, barns, and stables. Most of the cases reported were bites on the genitals or extremities. Several of the cases were operated upon under the mistaken diagnosis of perforating ulcer due to board-like rigidity of the abdomen. The victims of Black Widow spider bites become desperately ill and some die.

The apiarist also has his stings from the honey bee (*Apis mellifera*).

OCCUPATIONAL DISEASES AMONG CATTLE AND DAIRY MEN DUE TO ANIMAL INFECTIONS

One of the earliest skin lesions found on the hands of dairy maids was cowpox or vaccinia, which Edward Jenner observed. His studies led to his epoch-making work on vaccination for the prevention of smallpox.

Glanders, a highly infectious disease due to *Bacillus mallei*, found among horses, mules and asses, is frequently conveyed to man. The author has had 2 cases among farmers, 1 resulting fatally.

Anthrax, or malignant pustule, is occasionally found among shepherds, shearers and farm laborers. Out of 143 deaths tabulated by Andrews from 1910 to 1917 in U. S. Registration Area by

occupation, 42 were ranchers and farmers. Actinomycosis, known as lumpy jaw in cattle, caused by the *Actinomyces bovis*, is occasionally transmitted to herders and dairy men and cattle men.

In California, coccidioidal granuloma, due to the *Coccidioides immitis*, closely resembling blastomyces, is a disease found primarily among farmers who contracted the infection in the course of their occupational duties. Tularemia is more common in rural districts, especially among farmers coming in contact with rabbits and the vectors that carry the infection. Tularemia must, therefore, be classified as an occupational disease.

R. T. Legge in 1921 investigated the abrasive action of figs on the cuticle of the operators picking and packing. The dermatitis of the fingers is undoubtedly due to the latex in the stems and skin of the fruit which possesses an enzyme having a proteolytic action on the skin.

Investigations by K. Meyer of the Hooper Foundation, University of California, San Francisco, in a botulism outbreak, revealed the fact that many cases of this disease were found among rural inhabitants who had eaten home-packed vegetables.

A form of eczema is observed among truck gardeners during the picking season of ripe tomatoes; it is also found in more pronounced form among peelers of tomatoes in canneries. It is believed that the irritating factor is the citric acid in the fruit, and can be relieved by dipping the hands in a mild alkaline solution.

During the past spring, when the daffodils were blooming, a farmer in San Mateo County complained of his pickers and packers having a dermatitis venenata, a rash with papules, vesicles, and at times pustules, due to an irritant probably in the sap of the flower stalks.

OCCUPATIONAL DISEASE AS A RESULT OF INSECTICIDES AND CHEMICAL POISONS

The horticulturist today, to secure good crops, is constantly waging war on enemies which bring disease and death to his trees, vines, and other forms of plant life. The various scales, mildew and fungus diseases, the bacteria, the destructive pests, such as flying and crawling insects, rodents and birds, require his utmost vigilance.

Among cattlemen in the Rocky Mountain states, Rocky Mountain spotted fever is quite common. The disease is transmitted by the *Dermacentor andersoni* (tick). The Supreme Court of Idaho, in 1932, upheld the Industrial Accident Board in its decision to grant an award to the beneficiaries of a man, who in the course of his employment was bitten by an infected tick and subsequently died.

Foot and mouth disease, or aphthous fever, a contagious disease found among pigs, cattle, sheep, and goats, due to an ultra-microscopic organism, is contracted by man, especially workers engaged in animal husbandry and dairy work. The commonest disease among milkers, dairymen and cattle raisers is undulant fever, found principally in dairy cattle, goats, and hogs. True Malta fever is due to the organism *Brucella melitensis*, and a similar disease in cattle and hogs to *Brucella abortus*. It has a mortality of 2 to 13 per cent. The only cases I have treated were among workers on dairy farms.

OCCUPATIONAL DISEASES AMONG FRUIT HANDLERS

H. Sutherland-Campbell brought to the attention of the profession the fact that parochia among orange workers is due to a fungus of the family Murovaceae. Workers are especially liable whose fingers come in contact with the pulp or juice of the orange, particularly that of culls.

L. B. Kingery and C. H. Thienes in 1925 found among fruit canners in the Pacific Northwest, a paronchia and dermatitis of the hands due to a mycelial infection. This disease has been called by the workers "fruit poisoning."

Poultry are infected with lice, sheep and livestock with mange and other parasitical infections. Creosol in some form is used as dips. Sheep dip, which is an arsenite of soda containing arsenic sulphide and free arsenious acid produces a characteristic rash on the exposed parts of the sheepman's body. Cases of perforations of the septum due to this irritant have been reported.

There are sprays intended for the destruction of chewing and boring insects and their larvae which contain principally arsenate of lead and Paris green. Kerosene and whale oil soap are used for insects that are destroyed by choking their respiratory apparatus. The scales and fungus diseases are checked by carbonate of copper, Bordeaux mixture, and nicotine. The fumigants are the deadly cyanide gas and sulphur. Occasionally a worker is accidentally poisoned, as was the case recently when cyanide fumigation was being used against a vine leaf pest in California.

In using arsenate of lead for effective spraying, there is the dual danger of either lead or arsenic poisoning. I recently observed the case of a horticulturist who had been spraying trees. Some of the spray had gotten on his face and hands, producing a typical arsenical dermatitis. Many workers develop scleroderma or warts during the spraying season.

Paris green is an arsenate of copper and is used extensively for spraying fruit trees, vines, and vegetables. It is responsible for producing typical arsenical symptoms, and causing skin irritation. Recently a case of amblyopia was reported in a young farmer who

was using nicotine in a spray for fruit pests.

Of the rodenticides, phosphorus, thallium sulphate, carbon bisulphide, and carbon monoxide gas are used. The records show many cases of poisoning and some deaths from the use of these toxic substances.

Several of the chemical agents used as weed killers produce dermatitis and are poisonous.

PREVENTIVE MEASURES

When consulting the Agricultural Index, one cannot help being impressed with the amount of research published annually on the various phases of agricultural activity and economics; dairying, animal husbandry, veterinary science, agronomy, and horticulture. However, virtually nothing is to be found pertaining to the farmer himself, his safety, and the prevention of his occupational diseases. The purpose of this paper is to point out the occupational hazards the agriculturist encounters daily, and their prevention by accepted methods. Every state board of health, workmen's compensation commission, state and agricultural college, farm advisory board, etc., should use its offices and bulletins to spread information concerning the methods by which the occupational hazards of the agriculturist may be decreased.

The man who knows the dangers he is likely to encounter, should study them just as the physician, who comes in contact with infectious diseases, is constantly on the alert to prevent them.

He should wear proper clothing, not only to protect his body from cold and heat, but proper boots to protect his feet from infection, gloves to protect his hands from chemicals and other agents that may produce dermatitis, and insulated hats to protect himself from heat stroke.

The various insecticides and rodenticides contain lead, arsenic, and nicotine, principally—all deadly poisons; and every one handling such agents must be warned of the effects they have on the human body. He should not only know the dangers, but the common antidotes and, in case of accident, what to do before the doctor arrives.

The sanitation of the farm is an important problem in rural public health procedure. It includes the control of malaria by established methods of mosquito control, of dysentery and diarrhea by preventing fly breeding through agencies to collect materials such as barnyard manure, garbage, and human wastes. Toilets with septic tanks avoid soil pollution from human wastes, and thus control hookworm. The prevention of accidents is accomplished by safety measures.

I have pointed out the occupational hazards of the agricultural industry and have presented the dangers that arise from accidents, diseases from farm animals and plant life and the hazards of chemical and physical agents used in agricultural pursuits. These hazards can be reduced fully two-thirds by the application of the measures used successfully by urban industrial concerns.

A School Health Program as an Educational Activity*

DON W. GUDAKUNST, M.D., F.A.P.H.A. (*Life Member*)

Director School Health Service, Department of Health, Detroit, Mich.

DUE to the complexity of modern social existence there is an obligation placed upon the educational forces of the community to direct those factors that determine the limits of health of individuals. These forces must be studied not from the viewpoint of a school alone, but as a community problem, when attempting to alter the practices of a group. The social forces of the community should be utilized. More specifically, this can be stated by saying that the improvement of health of the school child must bring into play alteration in the home and utilization of the facilities of the physicians of the community.

At its inception the school health program started with environmental factors. The program had utilitarian aims entirely. Sanitation, ventilation, and fire hazards were the first problems to be considered. Then was added the attempt to control communicable diseases. This was a little more complex, involving problems of an individual nature as well as those of environment and sanitation. As the work of health in our school systems become more extensive, more and more of the personal elements were given greater consideration. Individual resistance to disease was considered—the presence of defects of structure or development in children was

considered. Personal hygiene—eating, bathing, sleeping, waste elimination—all came to be considered as within the scope of a school health program.

This was as it should be, for with the advance of and the change in civilization and the mode of living, these personal problems became more important, not only to the individual but also to the community. Physical defects of children had to be corrected; individual resistance to disease had to be raised; a healthy efficient body structure had to be promoted.

The success of the health program in respect to improvement of the school plant and its environment was great. The technics used in bringing about these changes were successful. The school board appropriated money to make the improvements. The board of education supervised and demanded the alteration of old plants and the proper construction of new ones. Then, with the inclusion of newer items in the health program, the technic which had been so successful in the reduction of hazards, due to the faulty environmental factors, were very largely carried over. These technics of purchasing, demanding adherence to accepted specifications, alteration of existing faults by expenditure of public funds, were applied to the problems of purely personal health. The correction of visual defects, diseased teeth and tonsils, the immunization against certain diseases, the installation of bathing facilities, the establishment

* Read at a Joint Session of Public Health Education and Child Hygiene Sections of the American Public Health Association at the Sixty-third Annual Meeting in Pasadena, Calif., September 4, 1934.

of school lunches, all were undertaken in a very extensive manner on a purchase basis.

There has been widespread realization of the inadequacy of this plan of trying to purchase personal health. Few, if any, of the old problems were completely solved. The buying of health for school children served merely as a stop gap. New methods of approach have been developed. These are educational in nature and involve exceedingly simple principles. First, there is the development of a realization as to what constitutes good health; second, of showing people how to use their own initiative and existing agencies so as to secure this good health. Something must be substituted for the attempt to improve personal health by purchasing it for the individual child. The objectives and technic of health education need to be altered.

The first objective of any constructive school health program should be teaching the pupils and the community what constitutes good health. Next, there should be held as an objective of health education the development of an appreciation of what constitutes proper health advice. In this day and age of uncontrolled advertising of false and even dangerous medical claims, the exercise of great care and judgment is required to select the true from the false. It may be more important, for the social well-being of a school child, for him to know that diabetes can only be controlled by the skilled care of a physician, and cannot be helped by some advertised nostrum, than it is for that person to know that the capital of Michigan is Lansing and not Detroit. This change in health education is accomplished only with difficulty among certain people. It has been such a short time since all medical care was a court of last appeal—the doctor was called in only when all else had failed. The educational forces of this country have not

as yet taught people what constitutes proper health advice.

Another objective to be gained through the medium of health education in the schools is the establishment of a self-reliance in respect to securing health aid. The individual must be made familiar with and know how to make the most of the various remedial and prophylactic health forces of the community. It is not sufficient that the child have a physical defect removed or corrected by the school authorities. This is not education. This is repair, frequently instituted for the benefit of the school and not the child. That child must not be taught to lean upon the school nurse, physician, dentist, or nutritionist for health counsel, supervision, and treatment. It is the responsibility of the family to see to it that the child is placed in the best possible physical condition, not only so that he can secure the maximum from school, but also so that he can secure the most from all of life's experiences. By teaching the child and his family to rely completely upon the school health service staff for such things as physical examination, immunization, correction of dental defects, correction of any or all other physical ailments, that child and that family have been taught to rely upon a force that in but a very few years will be denied them. In this country no person can expect such medical and expert health care from the State after leaving school. The child and his family should be taught not only the need for medical care, but next they must be taught where and how to secure such care from the existing forces of the community. Without this latter part there will be no carry-over force to the teaching of the first part. The giving of this care by the school does nothing toward establishing a knowledge of the method of securing proper medical care. It does not educate and train a child to be a self-reliant citizen.

It tends to cause him to lean upon a force that suddenly is withdrawn when his school days are ended.

No satisfactory system has as yet been worked out in any country whereby the State can assume the responsibility in its entirety for the health practices and care of the people of that country. A division of authority must be made, separating those things which are the obligations of the State and those which are the obligations of the individual. The line of demarcation must be sharp, although from time to time changing circumstances must alter the location of the dividing line separating the one from the other. The school and educational systems, as the agents of the State, should see to it that those things over which the individual can, by the very nature of things, have no control are adequately supervised. There is that group of things over which the State has only part control and the individual has part. There must not be usurpation of authority by either the State or the individual in this category of activities. Then, there are those medical problems that are entirely individual and personal. It is but the duty of the school to educate the child in this respect and not actually to practise medicine.

The minimal staff to carry on the needs of the school system in respect to its physical health program must consist of persons trained in various lines. First, there is the physician with his agent, the nurse. Then, there is the teacher. The teacher is the most important of all in actually conducting the program. It is her duty to translate to the children and the community the principles of health as laid down by the school physician.

In considering the duties of the teacher we should rather think of the opportunities. Teaching of health is not and cannot be the rôle of any one person. No one teacher can conduct a course in health and feel that this is

all that there is to the problem. Health teaching must be integrated with all possible phases of school and community activity. In our schools it must be woven throughout the entire fabric of the plan of education. Every teacher must play a part. The first thing that should be done is to acquaint each teacher with each child under her supervision. Each teacher should know the limitations and potentialities of each of her children. She must be intimately acquainted with their physical defects. She may acquire this information in several ways—through being informed of them by the nurse; through watching a physician make the health examination; or, what seems the most satisfactory, through actually inspecting each child herself. The experience gained and the appreciation of the individual child's problems are so much greater if the teacher actually discovers them herself. The more the teacher recognizes these things in individual children, the more will health work become a living, vital force in moulding her method of handling the individual child. So, too, the more the teacher knows about these things, and the more she is able to do in taking part in a general health program, the more she can do to secure and further the correction of the existing physical defects of the group. If a teacher inspects the mouths of 100 children and finds that 75 or more of them are badly in need of dental care, there must be forced upon her a realization of the inadequacy of the existing dental program of the community.

It is not the duty of the teacher to diagnose and prescribe for physical defects. All she can do is teach the child and the community what constitutes good health and the method for securing improvement. In this she should be aided by the physician of the school.

It is not the duty of the school physician to diagnose and treat these same physical defects, for his rôle while in

the school must be one of education along the lines for which his special training best fits him. It is his duty to point out the way to correct and prevent. Frequently this is a much harder task than it would be to correct the fault, but he must at all times remember that he is but a part of the educational program dealing with the teaching of an entire community in the methods of appreciating, securing, and holding good health.

Treatment of the existing pathological condition is essential, but treatment in itself is not striking at the root of the evil. No child comes to school with a fault of physical structure or of health practice because that child wishes to have such a defect. It is present because there is a more fundamental fault. The parents and family are ignorant of one or more of several things. First, they may not know of the presence of or the significance of the defect. This is in itself of serious implication. It means that this family is lacking in the first fundamental of health education—they do not know what constitutes good health.

If the family is aware of the defect and still does nothing about it, once more the trouble is a correctable deficiency on the part of the family. They do not know how to secure the indicated medical or dental attention, the importance of such care, or how to utilize the existing corrective health forces of the community. Poverty is seldom, if ever, a valid excuse. In most communities there are welfare and relief agencies ready and willing to give care to those who are unable to secure it through other channels. If there are no such agencies operating, then again there is a fault of education of the community that is of far greater import than the mere presence of the uncorrected physical defects in school children. Here is opportunity for the school health workers to line up the existing forces

and agencies of the community to organize such corrective and treatment clinics as the welfare of that community demands. Affording treatment to the school child within the schools or by the school agencies, under such circumstances, is an extremely short-sighted public health policy, ignoring the needs of the other four-fifths of the community's population.

In following out a policy of education of the parents and the community both to provide and seek remedial treatment, the school health forces are working on a far-sighted plan. There is a carry-over value in this plan. If a mother is taught the importance of disease and is provided with both the incentive and the means of securing a correction for one school child it is not too much to hope that same parent will afford the same care for the younger children of the family; nor is it too much to expect that other parents will likewise learn how to secure medical aid for their children. The oncoming children will enter school in just that much better condition.

The ultimate in good care for children can come from having all the medical forces of a community utilized to their fullest in correcting and preventing defects of the children. The family and the child should be taught to go to a physician not only for correction and treatment of existing conditions, but they should be so guided that they will go to them for the periodic examination. The resources of the school should be reserved for the detection of defects in the children of parents who have not as yet learned to follow this practice. The child who is under the constant supervision of a private physician is not in need of examination and diagnosis by the school teacher, nurse, or physician, providing, of course, that there has been developed a satisfactory system of notification of the school of the uncorrected defects that

are apt to interfere with or call for a modification in the school curriculum.

The school physician should see to it that the medical forces of the community are organized and prepared to care for this assignment. The private physicians should be able to examine in a satisfactory and complete manner all children who present themselves. This service should be available at a price within the means of every family. It is not implied that a low or no fee should be charged, but it is essential that different arrangements be made to care for the different economic groups. Care should be consistent with and of a type that is available to that group at all times. There is no sense in sending the chronic pauper to the offices of the exclusive specialist for an examination if his family cannot call upon that same specialist for its medical care at all times. Attempting to do this causes unrest and dissatisfaction on the part of the patient and the physician. An arrangement must be worked out that will serve all members of that family at all times. The completion of such arrangements must, if need be, be carried out by the school physician and his staff. It is serving the school child to the greatest extent to see to it that medical care and attention are at all times available for all members of the school child's family. Picking out one or more members of that family for 9 or 10 months of the year for a few years of life is a most short-sighted policy. Let the schools educate the people as to the needs of medical care and the means of securing it; let them elicit and develop a sense of responsibility for health on the part of the family; let them prepare the medical profession to assume its obligation; and then most of the problems of school health will be solved in a permanent manner.

One of the greatest aids in securing the assistance of the group of practising

physicians of the community is to acquaint each physician with the school, its plant, teachers, curriculum, and aims. A concerted effort is necessary to accomplish this. Every physician of the community should be acquainted with these things, and it would be far better if every physician were allowed to take an active part in the health service of the school system. This participation should, of course, be under the instruction and guidance of the specially trained school physician. Just as it works to the advantage of the school child's health to have the teacher play an ever increasing rôle in the detection of defects and in the education of parents in the need for correction, so, too, does it act beneficially to have the practising physicians of the community play a similar part. They should become acquainted with the school child, his physical health problems, and the facilities of the school to care for and meet these problems.

The school health service caring for the control of communicable diseases is identical in its set-up with that for the control and correction of physical defects. Again, the teacher, nurse, and doctor must all play their parts. No one can do his share without the full coöperation of the others. Again, the educational factor is of the greatest importance. The program starts with the teacher and her activities. The teacher inspection of children is the start. But this inspection as a formal, comprehensive, searching program must be carried on in the home and not in the school. The teacher inspection should serve as a check on that of the parents. It should be a device detecting the failures on the part of the parents. Parents should not be taught to send their children to school in order to find out what is wrong with them, nor should parents be taught to assume that the school will take the responsibility of picking out those with communicable

diseases. If a child with a communicable disease is sent to school there is bound to be exposure of others. Parents must be taught how to detect signs of illness. When a parent fails in his duty and responsibility, a duty to his own child and a responsibility to the entire community, then the teacher should be in a position to detect this failure at once. This means that the teacher too has to conduct a second inspection. Having detected a child ill with symptoms of a communicable disease, but part of the task is done. The fault that lies back of this child's coming to school, endangering his own and the health of others, must be corrected. That can be done only in the home. That child should be taken home by the nurse and a full explanation given to the parents of what has happened and the danger resulting. The nurse because of her special training in this respect is in a position to instruct the mother as to the signs and symptoms of communicable diseases.

Immunization against smallpox and diphtheria, and at times and in certain localities against scarlet fever and typhoid, should have the same underlying philosophy as the routine program for the control of communicable disease. The vaccination of a child, the injection of toxoid, and other prophylactic medical practices, are not

primary functions of a board of education. They have little or no educational implication in themselves. As all too frequently conducted, they tend to tear down the laboriously built up teaching of self reliance. When diphtheria immunization is done in school and as a school project it should be conducted as a supplement to a general community health program, and every child that has to be immunized in school should be looked upon as a failure in the general health education program. Steps should then be taken to correct and lessen these failures. This same thought should apply to all other prophylactic practices that are carried on within the confines of the school.

A school health program conducted as an isolated bit of effort is doomed to failure. A successful school health program must be built around the full life of the school child. It must have as active participants not only the school doctor, nurse, and teacher, but also the parents, the physicians of the community, the social and welfare agencies, and all other forces that can influence the physical well-being of the entire community. The pupils should have a series of experiences of real learning, situations which can give them and their families an opportunity to plan their own solutions for the present and future problems.

Application of the Neufeld Reaction to the Identification of Types of Pneumococci*

With the Use of Antisera for Thirty-Two Types

GEORGIA M. COOPER AND ANNABEL W. WALTER

Bureau of Laboratories, Department of Health, New York, N. Y.

AS clinical results show that success in the treatment of pneumococcic pneumonia cases with specific antisera is dependent to a large degree on the early administration of the serum, the rapid identification of the infecting organism by a reliable method is of great importance. Neufeld¹ in 1902 reported that the capsules of pneumococci in contact with specific antiserum become swollen and more distinct in outline and develop a ground-glass appearance. In 1931, Neufeld and Etinger-Tulczynska² identified types of pneumococci in mixed cultures by this reaction and stated that antisera prepared in rabbits rather than in horses should be used. Armstrong,³ and Logan and Smeall⁴ in 1932, independently, reported that the reaction could be applied practically to the determination of the type of pneumococcus directly in sputum. Etinger-Tulczynska,⁵ in 1933, in a detailed study of the reaction, noted that antisera produced in rabbits caused the formation of broader, more strongly refractive layers around the cocci than the antisera produced in horses. The precipi-

tates formed by mixtures of pneumococcic soluble specific substance with horse and with rabbit antiserum differed when examined microscopically; that with horse antiserum appeared as granular heaps and that with rabbit antiserum as glistening drops and flakes.

Sabin (1933)⁶ made a practical application of the Neufeld reaction to the diagnosis of 100 cases of lobar pneumonia. With Type I and Type II antisera (rabbit) he was able to identify Type I or Type II in 53 cases and obtained no reaction in 47 cases which were subsequently shown to be caused by other types.

Beckler and MacLeod (1934)⁷ have examined 760 specimens using antisera for Types I to XXXII with an error estimated to be not over 1 to 2 per cent.

Notwithstanding the reports of others that horse antiserum was unsatisfactory, we made a trial of refined antisera which had been prepared from high grade horse antisera by concentration to one-tenth its former volume. The layers produced about the cocci were as broad as, or broader than, those formed in rabbit antisera. However, with both concentrated and unconcentrated horse antisera, the swollen capsules were less refractive than those formed in rabbit

* Read before the Laboratory Section of the American Public Health Association at the Sixty-third Annual Meeting in Pasadena, Calif., September 4, 1934.

antiserum. Furthermore, the antisera produced in horses generally gave considerable cross-reactions and consequently were unreliable. We find in many cases the characteristic appearance of the capsule in contact with its specific rabbit antiserum more dependable than mere increase in the size of the capsule.

Antisera produced in rabbits, with a very few exceptions, were highly specific when precautions were observed to avoid the injection of any considerable amount of autolysate and of any trace of soluble specific substance of other types.

The method of producing antisera as developed and carried out by Miss Rosenstein in this laboratory is given here in full because of the many requests which we have had for details.

Pneumococci are transplanted from stock cultures in beef heart phosphate (0.2%) broth containing 3 per cent citrated horse blood into tubes containing beef heart phosphate broth without blood and are incubated about 24 hours. From these preliminary cultures, transplants are made into bottles of beef heart phosphate broth for the antigens to be used for injection.

These cultures are incubated 18 hours. They are then centrifugalized and the sediment taken up in a solution of 0.5 per cent formalin in salt solution in such an amount that the sediment from 10 c.c. of culture is contained in 1 c.c. of suspension. The vaccine is held at room temperature for 4 to 5 hours to aid in killing the organisms, and then is stored in the icebox until used. Sufficient vaccine for the series of injections is prepared at one time.

Injections of rabbits are given intravenously on 3 consecutive days followed by 4 days of rest. A normal bleeding is made immediately before the first injection. The quantities injected the 1st week are: sediment from $2\frac{1}{2}$ c.c. culture (0.25 c.c. vaccine), sediment from 5 c.c. culture (0.5 c.c. vaccine), and sediment from 10 c.c. culture (1 c.c. vaccine). Beginning with the 2nd week, the sediment from 10 c.c. (1 c.c. vaccine) is injected each time.

When it seems advisable, trial bleedings are made on the 3rd day after the last day of the injection series in order that the schedule may not be interrupted if the titer of the

serum proves too low. The first trial bleeding is made after the fourth series of injections (the twelfth injection).

The minimum titer requirement which we have adopted for a serum is that it shall strongly agglutinate the strain with which it was prepared in a dilution at least of 1-200.

Agglutination titrations are carried out with equal parts of serum dilutions and formalized antigen or 18 hour live cultures diluted to make thin suspensions of approximately uniform opacity, which are mixed and are incubated 2 hours at 55° C. The agglutination reactions are read. Tests are placed in icebox overnight and again read.

Rabbits are bled on the 6th to 10th day after the last injection.

Each antiserum is tested to determine its ability to cause a characteristic swelling of pneumococci of the homologous type and its freedom from cross-reactions.

Very bad cross-reactions result from the indiscriminate use of syringes. It is important, therefore, to reserve a separate syringe for each type for the period of immunization. Before a syringe is used for injections of another type it should be thoroughly scoured and cleaned. Through a failure of one of our workers to appreciate the importance of special care, a number of antisera were made, in the preparation of which syringes which had not been specially treated to remove all traces of the vaccines previously injected were interchanged from day to day. The syringes were rinsed by drawing water in and out and were sterilized. The antisera prepared at this time reacted so strongly upon the heterologous type strains which were being used for injection at the same time that in one or two instances the type for which the antiserum was prepared could be determined only from the records. A similar experience with like results was related to us as having occurred in another laboratory. It seems probable that some of the failures to secure reciprocally specific antisera for Types I and II from rabbits which have been reported to us may be explained in this way. It appears that a very small amount of antigenic sub-

TABLE I

EXAMPLE OF AN APPLICATION OF THE NEUFELD REACTION TO THE IDENTIFICATION OF THE TYPE OF PNEUMOCOCCUS IN SPUTUM WITH THE USE OF COMBINATIONS OF ANTISERA

stance may stimulate the production of antibodies sufficiently to cause marked reactions.

Some difficulty was encountered in the production of Type III antisera which would be free of reaction on Type VIII strains. Certain Type III strains are especially active in stimulating the production of such cross-reacting sera. The old Type III "R3" stock strain which we use seems to be more than ordinarily free from this quality. Where immunization was continued longer than usual, even with this strain some of the antisera produced reacted somewhat on Type VIII strains. Highly specific antisera can be prepared and only such should be employed.

Representative strains of Types I to XXXII were found to react in a satisfactory manner with their homologous antisera.

With a view to decreasing the labor involved in the use of so many monovalent antisera in separate tests, combinations of 5 or 6, or of 10 or 12 different antisera were tried. At first, we tried the combinations in amounts similar to the monovalent antisera and obtained a fair percentage of positive results, but failed to identify the type in several sputa which were loaded with pneumococci. These sputa were subsequently found to give very definite reactions with homologous monovalent antisera. When relatively larger quantities of the combinations were then tried with these sputa, it was found that the greater the proportion of serum, the more marked were the reactions. It is probable that when large amounts of soluble specific substance from disintegrated pneumococci are in the sputum, antibodies are neutralized so that where only relatively

CHART I—Pneumococci with normal capsules.
No reaction.

CHART II—Pneumococci with capsules swollen.
Positive reaction.

small amounts are present, insufficient antibody remains to cause a recognizable reaction with the individual organisms. With monovalent antisera a proportion of about 4 parts antiserum to 1 part of sputum, or other pathological material, generally gave satisfactory results; with combinations of sera, however, to obtain equally satisfactory results, a relatively greater amount, about in proportion to the number of antisera combined, *i.e.*, 20 to 40 times as much serum as sputum, was necessary. Satisfactory results can be obtained with pneumococci in cultures and in peritoneal washings of mice if a sufficiently large proportion of antiserum is employed.

Although, without question, where serum therapy is to be used, the examination for the type should be made at the earliest possible moment, the contention that "sputum should be typed not later than 2 hours after it is coughed up," is not valid. We found that the type could be determined in a majority of sputa considerably older than this. Specimens after storage in the icebox for over 2 weeks gave positive results.

Sputa kept at room temperature gave unsatisfactory results because of the overgrowth of other organisms.

The results⁸ reported at a meeting of the Society of American Bacteriologists in December, 1933, of the examination of a group of unselected sputa from 110 patients made 6 to 48 hours after collection illustrate the degree of success that is possible with such material. Positive findings were made in 84, *i.e.*, 76 per cent, and negative findings in 28 cases, 24 per cent. Of the latter, 6 were from respiratory conditions other than pneumonia. Of the 22 negative sputa from lobar pneumonia cases 7 were from patients 1 to 8 days after the crisis, and 5 had received serum treatment which may have influenced the results. No explanation for the negative findings in the other 10 is available, as the examinations were not repeated since they had been made, not with the object of making a diagnosis, but as a means of investigating the activity of certain sera.

We have found the following technic for carrying out the test satisfactory:

With a tiny loop or a straight wire place

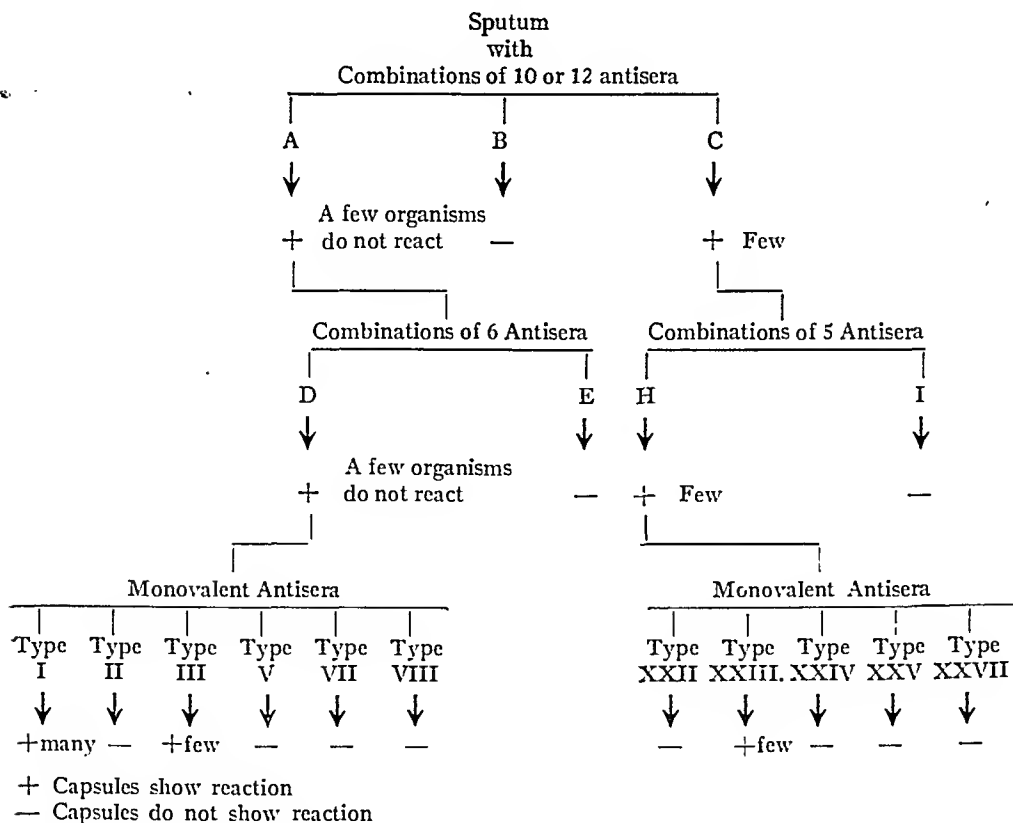

a very small amount of material on a cover glass, mix with 4 to 40 times the amount of serum as required and a standard loopful (0.01 c.c.) of Loeffler's methylene blue. Seal on a hollow-ground slide with cedar oil, place a drop of oil on the cover glass and examine with the oil immersion lens. Inverting the slides with the ends on side rests, and cover glasses down for a short time before examination seems to facilitate the examination, especially when the specimen is thin. The heavier elements, including the pneumococci, settle on the cover glass and may be more easily examined. A fairly good microscope is necessary and a powerful microscope light is a great aid. When only ordinary light is

available the drops may be placed on flat slides and covered with cover glasses. When the organisms are few they are somewhat more difficult to find in thin preparations.

The procedure is to observe the reactions with 3 combinations of 10 to 12 antisera among which Types I to XXXII are divided. If there is a reaction in one of the combinations, tests are carried out with 2 combinations each containing 5 or 6 of the antisera included in the combination with which the reaction was obtained. Finally tests are made with the individual mem-

TABLE II

EXAMPLE OF AN APPLICATION OF THE NEUFELD REACTION TO THE IDENTIFICATION OF THE TYPES OF PNEUMOCOCCI IN SPUTUM WHEN MORE THAN ONE TYPE IS PRESENT WITH THE USE OF COMBINATIONS OF ANTISERA

Diagnosis—Type I predominates. Types III and XXIII found in small numbers. Infecting agent probably Type I. It may be a mixed infection but the common occurrence of Types III and XXIII in the mouths of normal individuals makes this conclusion doubtful without further proof.

bers of the combination or combinations with which reactions were obtained. By this procedure, the type of pneumococcus, or if more than one type is present, the types of pneumococci, may be identified. If it is probable that only one type of pneumococcus is present, as for example in a spinal fluid from a case of pneumococcic meningitis, when a reaction has been obtained, examinations of other combinations or antisera may be omitted. This procedure may also be followed in the examination of sputa from pneumonia cases when all the pneumococcus-like organisms appear to react. We find that the examination of such specimens can be completed in less than an hour.

Type determination by the Neufeld reaction seems to be the most rapid and reliable method which has been devised. It has the advantage that it can be applied wherever suitable microscopic means are available, without other, more cumbersome, laboratory equipment. It has the further advantage that the approximate number of pneumococci present can be estimated, which is of some diagnostic and prognostic value. The identification of the organisms actually present in the sputum is more reliable than any method in which mice are employed, because, in mice, there is always danger that certain mouth pneumococci, which are more virulent for the mouse, may overgrow the infecting type of the case.

SUMMARY AND CONCLUSIONS

Capsules of pneumococci of Types I to XXXII are specifically reacted upon by homologous type specific antisera (rabbit).

Time and labor are lessened by making preliminary tests with combinations of the antisera.

Success with materials of different kinds containing pneumococci depends on making the tests with a relatively very small proportion of the material to a large proportion of the antiserum.

With care, suitable type specific antisera can be produced in rabbits.

Some lots of Type III antiserum notwithstanding special precautions in their preparation may react on type VIII pneumococci, therefore each lot should be tested for its specificity.

Generalized Public Health Nursing Service in Cities*

NAOMI DEUTSCH, R.N., F.A.P.H.A.

*Assistant Professor of Public Health Nursing, University of California,
Berkeley, Calif.*

IN the recently published *Survey of Public Health Nursing* by the National Organization for Public Health Nursing, evaluation has been made of the performance of public health nurses based upon a sampling of services throughout the country. This searching probe of accomplishments and shortcomings gives substantiating evidence of present public health nursing practices and their effectiveness in meeting community needs. Certain conclusions are presented from a study of 39 agencies which may have a direct bearing on future plans for the public health nurses' part in a community program for the prevention and control of syphilis.

The survey's analysis of home visits included 7 types of services; marked difference in the quality of performance was revealed. The service designated as "Disease Prevention, including Syphilis and Gonorrhea Control" ranks fifth in the list. Only 13 out of the 39 agencies surveyed "render supervision to some extent," to cases of syphilis. As in other related services in the community, such as hospitals, laboratories, clinics, and social agencies, public health nursing facilities are also inadequate in dealing with this gigantic problem

with forcefulness and vigor. This is especially striking in view of the widespread prevalence of this disease and the knowledge possessed regarding its prevention, permanent arrest, and cure.

What are the difficulties in its control? How can the administration and practice of public health nursing services be made more effective with respect to this pressing public health problem? A clue to the answer to these questions may be found in this survey which indicates those factors in the performance of public health nursing which might be used as a foundation upon which to build and expand the public health nursing activities in a social hygiene program.

It is a noteworthy fact that the prenatal visit ranks first in the list according to quality of performance. This is of particular interest since the general conclusions of the survey state that the home visits in which health supervision and teaching form a major part rank lower than services in which bedside care is given. Yet the prenatal visit is primarily educational. The rôle of the nurse when making home visits for the control of syphilis is certainly that of teacher, yet these visits rank fifth. It is not difficult to find the reason for this apparent anomaly. Studies, demonstrations, and opportunity for research over a period of years have made available definite knowledge regarding the content and

* Read at a Joint Session of the American Social Hygiene Association and the Public Health Nursing Section of the American Public Health Association at the Sixty-third Annual Meeting in Pasadena, Calif., September 3, 1935.

method of the prenatal home visit. The Maternity Center Association has offered supervised field experience and has published briefs and outlines, both for use in the home visit and for group instruction. Other material from the Children's Bureau and from insurance companies has made possible the distribution of current and specific information regarding the procedures and technics in prenatal care, both in urban and remote rural areas. Supervisors with special maternity experience and training are more frequently a part of the supervisory staffs of public health nursing agencies than for other types of services.

A similar plan of study needs to be undertaken to gain more specific knowledge regarding the program and performance of the public health nurse in venereal disease services. It is obvious that education in the medical and nursing facts of syphilis is a necessary prerequisite for intelligent participation and for a high quality of performance. The *Survey of Public Health Nursing* states that only about 7 per cent of the nurses from whom information was obtained had completed an accredited curriculum in public health nursing. Thus, outlines and briefs (perhaps a summary of Gladys L. Crain's articles published in the *Public Health Nursing Magazine*) should be made available to assist the nurse in enlarging her content and improving her teaching. Statements covering the technic of the interview, the attitude and administration of the clinic need to be included. Opportunities for field practice under the direction of specialized supervisors, and theoretical instruction through extension courses would be of great practical aid in improving the quality of this service. Constant good teaching, in the home and in the clinic, not just "telling," will overcome many of the difficulties entailed in case finding and case holding activities.

A second factor brought out in the Survey showing possibilities for future development in this program, is provided by the criteria upon which ratings are based. Approach ranks first. The importance of this as an asset in communicable disease control cannot be overestimated. Many authorities state that the immediate problem is the prevention of the further spread of infection. To accomplish this the coöperation of the patient is essential—gained through an attitude of consideration in the clinic and an understanding of the social factors involved; through the nurse's tactful and skillful home visit influencing the patient and family to assume their share of the responsibility for the successful termination of the long period of treatment. The good approach is a big element in bringing this about. The Survey defines approach as: "implying those intangible qualities of relationship with people which makes for a good or poor contact." Upon the nurse's approach often depends the finding of sources of infection and contacts who must be persuaded to seek medical advice, early diagnosis and treatment if needed. Since "approach" was universally found to rank high and is of such importance in the work, it would seem that public health nurses can contribute effectively to community programs for controlling syphilis and assist in adjusting the social and economic conditions causing their spread.

C.-E. A. Winslow, in his book, *A City Set on a Hill*, in the chapter on Venereal Disease, says: "The most important development in the venereal clinic during the demonstration period has been in the employment of two nurses for social service follow-up of cases."

Given better qualified and more proficient personnel, current authoritative manuals of instruction, supervisors with special preparation, opportunity for continued staff education through insti-

tutes and study courses—all these though of primary importance are still only part of a plan for the development of more effective case finding and case holding activities. Equally important is the type of administration.

Public health nursing services require efficient administrative direction, including adequate financing and coördinated and unified community relationships. To achieve this, a generalized nursing program is most suitable, consisting of several types of nursing services administered by one agency, each nurse giving all these types of service to families under her care. Again quoting from the Survey:

Since the goal in public health nursing, as in many services essential to the well-being of the population as a whole, is a comprehensive community program, the Committee strongly recommends that all public health nursing be carried by as few agencies as possible. Through a combination of agencies, as is self-evident and as has already been demonstrated, a service of a more uniformly high quality can be rendered in a community with provision for a more effective program of supervision and staff education, with less expenditure of money than when there are many independent services. The Survey shows beyond a shadow of a doubt that such provision is one of the greatest needs of the present moment.

A generalized public health nursing service would be of great administrative advantage in the problems associated with case finding and case holding. In setting up a plan to meet this community need and make it most productive, the nursing agency must take part in coöperative study, through representation on the Community Social Hygiene Council, together with representatives of official and nonofficial agencies. In such a council, programs are studied and plans made so that contributions of the agencies and the professions may be most effective. These programs are based upon current information and knowledge of the extent and cost of venereal disease, upon

knowledge of activities of organizations directed against them, upon a record of facilities for their diagnosis, treatment, and after-care, and upon methods of "quacks" to trap the credulous. Such centralized direction, under leadership of the health department, facilitates coördination and integration of medical and nursing services and more nearly approximates the production of a maximum service with a minimum of waste.

Syphilis is essentially a problem of the whole family and the modern definition of public health nursing, whatever the program, is based on its relation to the individual as a part of the family and of the community.

The public health nurse is well known to many families in her district. Her maternity program includes the supervision of the pregnant woman. The possibilities of eradicating congenital syphilis through treatment early in pregnancy is a challenging problem in which the private physician, the clinic, and the nurse unite forces. Other types of home visits offer equal opportunity to change the attitude of the family toward syphilis, so that delinquent clinic patients, wrong addresses, fictitious names, will not be the rule, but instead a coöperative and responsible attitude on the part of the family, the attainment of which is so gratifying when working toward the prevention of other communicable diseases.

An example illustrative of such family coöperation occurred during the recent poliomyelitis epidemic. Two young girls had, after months of planning, arrived at a girls' camp. The day after they left home their mother ascertained that a child, with whom they had been to a party the evening previous to their departure, had developed poliomyelitis. She notified the clinic doctor and the camp director and the children were brought home and isolated.

Venereal disease, of course, presents more difficult problems, in many ways,

than other communicable diseases. It is more difficult to persuade people to the same reasonableness of attitude regarding diagnosis and treatment as has been developed toward tuberculosis. But a technic adequate for social and medical ends is being developed. The greater use of the generalized public health nursing agency by physicians and clinics as an economical and effective channel through which the weak spot—in

the control of syphilis, namely the finding and holding of cases—can be strengthened. The rôle of the adequately prepared and supervised public health nurse as the interpreter of scientific knowledge in performing family health service under the direction of a generalized public health nursing agency should be of great assistance toward attaining the goals of preventive medicine and public health.

Deficient Hospital Service

THIRTY-ONE million persons in the United States live in areas which are seriously deficient in hospital and health services according to a nationwide study made by Alden B. Mills, managing editor of *The Modern Hospital*, and formerly executive secretary of the Committee on the Costs of Medical Care.

About 1,300 of the 3,073 counties in the United States have no general hospitals. Some do not need general hospitals since they are or can be served by hospitals in adjacent counties if the distance is not greater than 50 miles. Consequently in this study the United States is divided into areas with approximately 50 miles radii.

After careful study of all factors involved it was decided that rural populations require a minimum of 2 hospital beds per 1,000 population, although the study does not recommend or consider practical the building of general hospitals of less than 25 beds. For smaller areas it is suggested that "cottage hospitals" or central medical service offices be established.

There are 31,000,000 people and 29,000 physicians in areas that contain less than 2 hospital beds per 1,000 population and are more than 50 miles from a hospital center; there are 1,117,915 persons and 896 physicians in areas that have less than one-fourth of this ratio (0.5 hospital beds per 1,000 population), that there are 147 such 100 mile areas in the United States which have fewer than 2 hospital beds per 1,000 population and that there is an actual need of 22,000 additional hospital beds in these 147 areas if minimum standards are to be met.

W. S. Rankin, M.D., F.A.P.H.A., of the Duke Endowment, says that the community without hospital facilities has ceased to attract the young, well prepared physician, and that, if he is forced to locate in such a rural area, he stays no longer than necessary to enable him to move to a community providing hospital facilities and congenial professional surroundings. Herein lies the principal cause of the relative scarcity of physicians in rural communities.—*The Modern Hospital*, Mar., 1935.

Formation of Sanitary Districts in Recreation Areas*

W. W. CHANDLER

Chief Sanitary Inspector, Orange County Health Department, Calif.

SANITATION, sewage disposal, and garbage disposal in recreation areas in California constitute a problem which is largely unsolved; yet, upon its proper solution rests the future and the safety of these areas.

Regulation and control have been left principally to the counties in which these recreation areas exist and in part to the Federal Forestry Service where the recreation areas lie within national forests.

County ordinances covering rural sewage disposal are not always applicable because they do not take into account the type of soil structure and drainage common to the recreation area. Sewage disposal facilities which would be safe and entirely adequate in one place may be a menace to health in an area where the soil is shale and gravel and the terrain is precipitous. Although chemical toilets are necessary in some locations, the owners find them inconvenient and expensive to maintain. In some selected locations we have found that contamination can be prevented by the construction of septic tanks of proper capacity, made of concrete, with the effluent passed through a sand filter. Such alternatives as this are seldom pro-

vided for in our rural sanitation regulations. Few if any of these general ordinances deal with garbage and waste disposal, the enforcement of safe building, plumbing, and wiring regulations to reduce the fire hazard.

After careful study, we have concluded that the interests of the areas will be best served by the formation of sanitary districts within these recreation areas. In our county, one of these districts is now in process of formation, and others are soon to follow. We feel that a local district can best deal with the sanitary problems of the area, as soil conditions and terrain differ from one recreation area to another.

Ordinances passed by the sanitary board have the force and effect of law. If the character of one area permits the use of a septic tank with sand filter, and that of another requires chemical toilets, such differences can be provided for by the respective boards.

In addition the sanitary board can, through housing, plumbing, and wiring ordinances, control the housing conditions and, to a marked degree, the safety of the area. With a sanitary district functioning, it will no longer be possible for ramshackle, unsafe, and disreputable looking houses to be built, depreciating the value of better properties beside them and increasing the fire hazard by unsafe and illegal wiring. The danger of such wiring was brought to our attention forcibly by the recent

* Read at a Joint Session of the California Association of Sanitarians and the Public Health Engineering Section of the American Public Health Association at the Sixty-third Annual Meeting in Pasadena, Calif., September 4, 1934.

disastrous fire in the Arroyo Seco above Pasadena.

A sanitary district can, at small expense, provide for the proper disposal of garbage and waste (cans, etc.) at regular intervals. Throughout California we have witnessed the progressive spoiling of our recreation areas with improperly disposed garbage, old cans, papers, etc. Add to this the danger to public health from the breeding of flies and mosquitoes in garbage and old cans. In addition, open and improperly disposed of garbage is a lure to rats, mice, and ground squirrels, serving to increase their numbers materially and attract them to the recreation areas. This, in turn, increases the possibility of outbreaks of bubonic plague and relapsing fever, which are already endemic in our rat and ground squirrel population.

A sanitary district can materially aid in the beautifying of its area by passing an ordinance requiring the coralling and fencing of all domestic animals which are now permitted to wander about, destroying flowers and plants. The saving in the cost of fencing properties alone would pay the cost of this for many years. Still another advantage of a sanitary district is that it would be legally organized to enter into contracts with the federal government for the development and maintenance of water

supplies and in this regard, would exercise the function of a water district with the additional functions of general sanitation, garbage and sewage disposal, and housing regulations.

And now for the cost—We feel that the disposal of garbage, cans, and trash can be taken care of very cheaply. The rate is low by virtue of the fact that in the neighborhood of most areas there is a man who owns a truck and will haul and dispose of the garbage and refuse for about \$50 a month or less. I feel certain that there are few districts which cannot find a responsible neighborhood rancher who will be glad to get the work.

The inspections are and will continue to be the function of the county health department.

SUMMARY

California has not developed an adequate technic to regulate sanitation, garbage, and waste disposal, building construction, plumbing, and wiring in the recreation areas of the state.

General rural sanitation regulations are largely inapplicable to recreation areas where unusual soil and topographical conditions exist.

The formation of sanitary districts in these areas appears to be the most practical, all-inclusive, low cost solution of the problem.

Public Health Degrees Granted in 1934

THE Committee on Professional Education of the A.P.H.A. has compiled a list of colleges and universities in the United States and Canada which grant degrees in public health. The March issue of the *Journal*

carried a report on the number of degrees granted in 1934, as well as a comparison of 1932, 1933, and 1934 figures. Reprints are available free, and may be had on request to the Executive Office.

The Vitamin B Adventure

R. R. WILLIAMS

*Department of Physiological Chemistry, Teachers College,
Columbia University, New York, N. Y.*

THE study of vitamin B which I have been privileged to pursue since 1910, has been preëminently a co-operative enterprise. Nearly 40 years of effort by scores of workers in many lands have furnished its foundation, and the early precedent of collaborative effort has been followed in our recent work.

The major task in defining the structure of the vitamin was getting enough vitamin for study. In this part of the work, much of which was done in The Chemical Engineering Laboratory through Dr. Jackson's kindness, the aid of Mr. Waterman and Dr. Kereszteszy was indispensable, not only because of their resourcefulness but because of their stamina under seemingly endless disappointments. Miss Ammerman's skill in guiding the work by means of curative tests on polyneuritic rats was equally important.

We have produced about 12 gm. of vitamin crystals, of which 4 or 5 gm. have been used for structure work. Vastly more material would have been required some years ago before Pregl's micro-analytical methods were developed. These were applied very successfully to our problem under the supervision of Dr. Oskar Wintersteiner of the Columbia Medical School, New York.

A disaster of earlier years was turned to account in approaching the study of structure, for sulphur dioxide which destroyed the vitamin where it was used as a preservative for rice polish extracts,

proved a tool for neatly splitting the vitamin molecule into two pieces without producing any chips. The reactivity of the sulphur in the vitamin led Dr. H. T. Clarke of the College of Physicians and Surgeons, who has specialized in the field of organic sulphur compounds, to suggest the presence of a thiazole ring, or nucleus in it. The absorption of ultra-violet light by one of the pieces of the vitamin, obtained by sulphur dioxide splitting, was found to resemble very closely that of a synthetic thiazole. A little further work served to confirm Dr. Clarke's suggestion. This is the first time a thiazole ring has been found in nature and it is not difficult to imagine that its discovery may ultimately prove more important to biochemistry than the structure of the vitamin itself.

We have made unusual use of ultra-violet light absorption in this study, for the pyrimidine nucleus in the other piece of the vitamin was confirmed also by this means as applied by A. E. Ruehle of the Bell Laboratories.

In the meantime Dr. E. R. Buchman, working at Teachers College, New York, in Dr. Eddy's laboratory and Dr. Samuel Gurin had ascertained by classical organic methods the identity and location of the side chains which cling to the two nuclei. Dr. Buchman also applied the happy idea of a central pentavalent nitrogen atom through which the two nuclei are attached to one another. This was confirmed by potentiometric titrations by Mr. Ruehle

using a type of equipment developed for telephone corrosion studies.

Thus four distinct laboratories contributed personnel or facilities. If there had been need for other talents we should have sought them. Such is the coöperative principle in modern re-

search. Nor should we forget the Carnegie Corporation who very generously supplied funds, nor even the much maligned depression which afforded additional week-end leisure for the work to the Bell Laboratories' contingent.

This is not the interior of a cathedral, but a typical sewer tunnel under a Chicago business street. In some parts, the tunneling is more than 19 feet in diameter. This immense sewage disposal project, the largest of its kind in the world, is being financed with an allotment of \$42,000,000 from the Public Works Administration.

CLIMATIC AND OPERATIVE TREATMENT OF SPINAL TUBERCULOSIS*

EXCERPTED BY RICHARD A. BOLT, M.D., F.A.P.H.A.

Director, Cleveland Child Health Association, Cleveland, Ohio

IN a comprehensive paper on Climatic and Operative Treatment of Spinal Tuberculosis, Dr. Fred H. Albee † gives a summary of our knowledge of surgical tuberculosis.

"Although quite readily distinguishable from one another by cultural, morphological, and inoculation tests, the bovine and the human tubercle bacilli are undoubtedly of common origin. That the two organisms are both responsible for human tuberculosis has been demonstrated abundantly; although what percentage of infections is due to each is the subject of divergent opinions. Bacteriological investigations by reliable workers have demonstrated the relation of a large proportion of bovine infection to an infected milk supply and a young age incidence. This is a natural sequence of events. The chief article of diet at the age when osseous tuberculosis is most common is milk. If this staple food is contaminated by the bovine tubercle bacillus, its ingestion is very naturally followed by tuberculous disease of the lymphatic nodes, cervical and mesenteric, and from this focus, a distribution of the bacilli to the bones and joints readily follows.

"*Portals of Entry of the Bacilli*—Antenatal infection may be disregarded as an unlikely possibility. The two most accessible channels of inoculation are the respiratory and alimentary systems. The relative importance of the two is still under discussion but unquestionably varies with the time of life, the preponderance of surgical tuberculosis in children suggesting the probable ingestion source at that time, while in adults the process is reversed, pulmonary lesions becoming the commonest and suggesting the respiratory origin.

"Other less common means of entrance are

the tonsils, the pharynx, the skin (following wounds), the genitourinary passages and the teeth; in the pulp of carious teeth tubercle bacilli probably infect the submaxillary groups of lymph nodes.

"*Source of Infection of the Bones and Joints*—Direct infection of a bone or joint from without so rarely occurs as to be a negligible factor. The indirect avenues of invasion are of course the blood stream and the lymphatic system. Much important work has been done by investigators to determine whether one or both of these routes provided the path of infection and whether the bones and the joints were equally liable to invasion or stand in relation to one another as primary and secondary infections.

"From the mass of data accruing from these investigations, four conclusions may be drawn: (1) Experimental tuberculous lesions are difficult of production; (2) trauma is a relatively slight factor; (3) joints are much more susceptible to tuberculous infection than bones, and (4) the joints are infected through the medium of the blood stream.

"*Predisposition*—to the tuberculous condition may be exhibited by reason of (1) injury, (2) heredity, and (3) general causes.

"1. *Injury*—Although a history of previous injury is nearly always given, there is no doubt that in a certain number of cases traumatism is an important factor. The effect of injury may be felt in two ways: (a) by the production of a *locus minoris resistentiae* consequent upon a small effusion of blood and lymph in the cancellous tissue and a stagnation of the organism; and (b) where a preëxisting tuberculous lesion has been circumscribed, encapsulated and quiescent, trauma may provoke active spreading of the process and the production of an infiltrating tubercle; this, in the case of a tuberculous focus in or near the articular extremity of a bone, may cause extensive involvement of the neighboring joint. It is believed, however, that in the histories of tuberculous joint cases the frequent occurrence of trauma as a possible etiological factor is partly accounted

* Abstract of paper presented to the Midyear Conference of the International Society for Crippled Children, Tampa, Fla.

† Fred H. Albee, M.D., Sc.D., LL.D., New York City and Florida Medical Center, Venice, Fla.

for by the fact that emphasis is placed upon the injury because the joint was sensitive from the lesion already present.

"2. *Heredity*—The subject of direct heredity has aroused strong discussion, and although cases of apparently true congenital tuberculosis have been reported, it is believed that a tuberculous parent reacts upon its offspring in a less direct manner: (a) by actual transmission of the tuberculous virus to the subject during intra-uterine life (Baumgarten); (b) lowering of the vitality of the subject by reason of the impoverished state of the parent's blood; (c) a tuberculous parent stands as a constant source of infection by virtue of proximity to the child.

"3. *General Causes*—These all operate to lower the vitality of tissue and to render the soil fertile for the implantation and growth of the offending bacilli. Among the more important debilitating states are the exanthemata, influenza, inadequate feeding, and want of fresh air and sunshine.

"In the first place, it should be considered as a chronic lesion, with probable foci in other regions of the body, which may or may not precede it (the particular lesion under treatment).

"As a rule, conservative treatment takes priority over operative interference in osseous

tuberculosis (except in the case of tuberculous vertebrae where a bone-graft or fusing operation is indicated in every case) in contradistinction to the treatment of monarticular joint tuberculosis, in which condition the reverse is true, especially in children. Operative measures should, however, be undertaken before bone destruction, secondary infection with abscess and sinus formation have occurred, and when lardaceous disease is threatened, especially in adults.

"The marked curative effect of bony ankylosis upon any tuberculous joint is axiomatic in orthopedic surgery. Without ankylosis, an advanced tuberculous process in a joint can never be said to be cured. In planning treatment of tuberculous spines, it is therefore of extreme significance that, anatomically, we are dealing with joints under constant uncontrollable mechanical influences, such as respiration and involuntary muscle spasm. This fact contributes greatly to the spread of the tuberculous process, prevents cure and makes for the development of extensive deformity, known as hunch back. It not only makes it more difficult for nature to set up a protective ankylotic process, but also presents increasing difficulties to the surgeon who attempts to bring about immobilization by nonoperative conservative measures."

Compulsory Health Insurance in Germany

THE available evidence is overwhelming that the effect of compulsory health insurance on the German medical profession has been little short of disastrous. The literature on the question, mostly in the German language, is as impressive as it is often pathetic in its pessimism regarding the outlook for far-reaching reforms. As

has been well said in an article in *Science* of October 12, 1934: "The medical profession in Germany has fallen into disrepute." . . . and "If present conditions are allowed to continue much longer, medicine will sink into a bog of absolute inefficiency." —Frederick L. Hoffman, LL.D., *California & West. Med.*, Feb., 1935.

SOCIAL SECURITY AND PUBLIC HEALTH

THE Federal Government's attempt to provide security against the major hazards of life is not a new idea. From the standpoint of health it has been one of the major objectives of the public health movement from its inception. Recent events have served to dramatize the whole topic of social security, by reason of large scale participation of the Federal Government in local economic and social activities. This participation has necessarily raised many difficult and fundamental questions of social policy and group relationships. The Association should be keenly alive to its responsibility for being certain that any proposed legislation or programs are in accord with sound public health policy. This does not mean the mere protection of the "rights" of the public health worker. It does mean the extension of adequate health service to all of the population without undue weight being given to interests of any special group of workers.

The scope of the pending social legislation before Congress merits careful analysis and constructive thinking. It holds out great promise for large scale financial assistance for local medical and public health programs. At the same time, it brings to focus several important controversial problems of policy and relationships.

The availability of federal funds for local health programs is now generally accepted as sound policy, though the question of the effects of central control is still raised in many quarters. There seems no sound reason why the federal relationship should not leave ample local autonomy, and at the same time assist in securing adequately trained health workers, proper local administration and programs.

The proposal to include medical care of certain groups in the public health program raises a definitely controversial subject. Among public health workers there are those who contend that the activities of the health department should be confined strictly to a program of prevention. They are convinced that the inclusion of the care of sickness will tend to obscure, if not submerge, preventive activities. It seems certain that no additions to the public health program should

deflect attention from our responsibility to provide adequately for control of communicable diseases, sanitation, infancy and maternity service, school hygiene programs, and public health education.

The proposals for health insurance are not primarily public health measures, but attempts to provide sickness care. We are definitely concerned with those aspects of this question which relate to possibility that public health departments will be concerned in their administration. This does not imply that the public health worker does not recognize the great importance of adequate sickness service as a measure for health preservation. As at present proposed, sickness insurance is not a primary responsibility of the health worker. If and when real provisions for preventive services are included, this will change the situation.

The proposed social security legislation brings to the fore another field in which there has been increasing tension. We refer to the relationships between the medical and public health professions. There has been an increasing organized opposition by the medical group to certain activities of the public health group. This opposition has centered upon those activities of the health worker in which personal prevention services have been rendered to the individual through group organization. The proposals to include certain types of medical care in the public health program have intensified this opposition.

We are convinced that a large part of the difficulty is due to a lack of a permanent effective mechanism for real contact between the governing bodies of the two organized groups. Such an arrangement has been in successful operation in England for many years. It has resulted in excellent relationships between the two groups, mutually helpful support for legitimate group objectives and improved curative and prevention services for the whole nation. We would advocate the exploration of the possibility of applying this idea to our problem of relationships at once.

NEED OF A 1935 CENSUS

DURING periods of normal prosperity, there has been in the United States, a pronounced movement of population from farms and villages to the cities. During the current industrial depression, however, this movement has been reversed; thus, the Department of Agriculture reported in 1933 that the rural population, which previously had been declining, had reached a new maximum.¹

As a result of these and other abnormal migratory movements, recent population estimates made by the customary procedure, of projecting past intercensal increase into the future, yield figures for most intra-state areas which obviously carry serious errors. In recognition of these errors, the U. S. Bureau of the Census has felt unable to issue intra-state population estimates for 1934, and later years.

A bill calling for a federal census in 1934 was introduced into Congress, but was defeated, in spite of widespread support, apparently because of implications claimed to have a bearing upon the 1934 Congressional elections. That objection has now disappeared; and the demand for a census has therefore been revived, and a new bill has been introduced looking toward enumeration in the fall of 1935, or spring of 1936.

The Council of the Vital Statistics Section of the American Public Health Association on February 3 adopted a resolution in support of the census, and a

similar resolution has subsequently been approved by the Executive Board of the Association. It is hoped that as many members of the Association as possible will supplement this action by writing to their representatives in Congress and to the Secretary of Commerce, Hon. Daniel C. Roper. The resolution of the Executive Board follows:

WHEREAS, during recent years, abnormal population interchanges between cities and rural regions have rendered impracticable the estimation of intra-state populations by the usual methods, with the result that the U. S. Bureau of the Census has deemed it inadvisable to issue for 1934, and later years, the intra-state population estimates required for the calculation of death rates, morbidity rates, and numerous other measures of social welfare, therefore be it
RESOLVED that the Executive Board of the American Public Health Association urge that Congress and the President provide for a general population census in the year 1935.

THE REGISTRATION FEE AT ANNUAL MEETINGS

IT will be remembered that a fee for registration at our Annual Meeting was first established at Montreal in 1931. It is not out of order to review the reasoning of the Executive Board when the step was taken, as a background for the comments which will follow upon the Association's experience with the plan in the last 4 years and the hopes for the future.

Every member knows his Association is not endowed and that it is not wealthy. The dues he pays amount to only one-fourth of the total sum spent on him every year by the organization. In other words, the income from all classes of membership equals approximately \$25,000, while the Association expends \$100,000—the difference being made up by *Journal* advertising, by sales of commercial exhibit space, by sales of books, by grants from insurance companies and foundations, and by field service.

The membership dues have never been increased. In 1872, the year of the society's inauguration, membership dues were established at \$5 and have remained so to this day.

The Annual Meeting is an important Association function which unfortunately only a fraction of the membership finds it possible to attend. It is expensive to arrange and conduct. It must be self-supporting. Obviously, it would be unfair to distribute the costs over the entire membership by an increase in membership dues, as has been proposed on many occasions. The only equitable plan is to place a nominal charge upon those who receive actual, personal benefits through attendance at the Annual Meeting; therefore, the registration fee was the device employed to assure the necessary amount, over and above the income from the sale of exhibit space, for financing our convention.

Other factors influenced the Executive Board in the adoption of the registration fee. One was the tendency, inevitable under the circumstances, for an Annual Meeting city to be selected almost exclusively upon its financial possibilities. Can exhibit space be sold easily? Will the Local Committee guarantee to make up any deficit? These questions were paramount, though they were recognized as

being unworthy of promulgation by a scientific society with a professional dignity to maintain. The registration fee, it was urged, would make the Association more independent in considering its convention locations.

These arguments, and many others in favor of the registration fee plan, as valid today as they were 4 years ago, were presented again and again to the membership. How has the membership responded? Some kicked openly and manfully, as was their privilege. Most of these finally agreed that, as President Cleveland once said, "It was a condition and not a theory which confronted us." However, a study of the last three meetings has shown that many of our members, as well as those who take advantage of our meetings as guests, have evaded their responsibility. The following is not a pleasant picture, but the truth must be told.

At Washington, D. C., in 1932, there were 296 names on the program, of whom 207 were members and Fellows, yet only 158 of these registered. There were 89 non-members and only 18 of these registered.

At Indianapolis, there were 266 names on the program, of whom 204 were members and Fellows, with 152 registrations. There were 62 non-members, of whom only 11 registered.

At Pasadena, in 1934, there were 306 names on the program, of whom 220 were members and Fellows. Only 138 registered. There were 86 non-members, of whom 15 registered.

The picture is especially dismal because the figures given above apply to those who took advantage of program participation and the publicity resulting therefrom and at the same time ignored their obligation. Program time is a coveted privilege and surely those to whom it is given should have the interests of the Association sufficiently at heart to live up to its regulations.

The comparison between the names on the programs and the registration list is easily made and incontrovertible. It is impossible to check the number of members not on the program who also failed to register, but the assumption is that the percentages are about the same. This means, therefore, that probably there were in attendance at the last three annual meetings 30 per cent more members than the registration lists record. The proportion of unregistered to registered guests is undoubtedly even greater if the figures above are any criterion, and may be as high as 75 or 80 per cent.

This is a bad showing. It is unfair. There is no justification for it.

It is hard to believe that members and guests intentionally avoid registering because of the small sum of \$2.00 involved. The delegate receives infinitely more from attendance at the Annual Meeting than can be measured in dollars and cents. Every fair-minded member will admit it and ask himself if he wishes to be classed with those who accept the benefits of membership and withhold the support the Association deserves at his hands.

The Committee on Meetings and Publications, and the Executive Board, have been concerned over this problem. Recognizing the fundamental fairness of the registration fee and interpreting the attitude of the membership toward it as either carelessness or failure to understand properly its important function and necessity the Executive Board, at the instance of the Committee on Meetings and Publications, asks the *Journal* to explain again to our readers why the registration fee is necessary, and to urge them to support it. One hundred per cent coöperation depends upon such a simple thing as the determination of every delegate to register his attendance and pay his \$2.00.

When a regulation adopted by the governing body in good faith and in the

best interests of the society is repeatedly and thoughtlessly broken, it is incumbent upon the policy-making group to do one of two things, either repeal it or enforce it. In the case of the registration fee, the Executive Board has seen fit to decide to enforce it, even to the extent of admitting to the scientific sessions only those delegates who display badges, indicating that they have registered. Members who have faithfully lived up to every demand made upon them, and who will continue to do so, will undoubtedly on occasion be inconvenienced by this, as well as those uncoöperative ones who have made the regulation necessary. To the former apologies are extended in advance, and their forbearance bespoken.

The American Public Health Association has a record of achievement of which all members should be proud. It is an honor to belong to such an Association, and the very few foreigners who have been elected to Honorary Fellowship appreciate highly the honor paid them. Practically every advance in public health measures can be traced to members of our Association, and most of them have been acted on officially by our body.

May we not insist once more that membership in the American Public Health Association is an honor to be sought after? May we not appeal to the patriotism of our membership to induce them to register at our meetings and pay their fees and urge their non-member friends in attendance to do likewise?

PUBLIC HEALTH EDUCATION*

Flamboyant and Not Polite—
Mother and Child, London, does not seem to like public health education methods in the United States:

Health propaganda is to be studied at its flamboyant best in the United States of America, the cradle of this doubtful and difficult art; but a slavish imitation of American methods could never succeed in this country, where people are inclined to be affronted by the flamboyancy so effective in America, and where the approach must, above all things, be polite. To be fairly immune against the effect of the propaganda is perhaps a matter for self-congratulation, but it makes the propagandist's job a very difficult one.

The National Baby Week Council has done much to develop health propaganda in this country. It has experimented with various methods and has encouraged local enterprise. It is helping to create a new style, authoritative yet conservative, a style which manages to affect British opinion without offending reticence.

In *Mother and Child*, 5, Tavistock Sq., London, W. C. 1. Feb., 1935. 9d. a copy.

"Medicine Men Take to the Air"
—Under this title, *Business Week* tells about the rapid increase in the use of broadcast time by drug and cosmetic companies.

Some trade observers suggest that drug men are rediscovering the "medicine man" selling technic. But, says *Business Week*:

Others see in it more sinister implications. Curative and therapeutic claims, they point out, can be advanced with considerably less risk over the air than through the medium of the printed page. Censors have more difficulty checking them beforehand; critics find it less easy to prove a case against them

afterward. And during the past year, because of the agitation over new food and drug legislation, curative and therapeutic claims have been subjected to far more exacting scrutiny than ever before—both by publishers and by the advertising review committee of the Proprietary Association which claims that it has inspected 27 millions' worth of advertising in the past 5 months.

The editor credits radio with efforts in the direction of censorship of claims for cures.

Radio's troubles with curative and therapeutic claims are not, however, limited solely to the broadcasts sponsored by the drug and cosmetic manufacturers. Apparently encouraged ("challenged" might be the better word) by the success of these programs, food sponsors are emphasizing with growing insistence the health values of their products. Nor are these claims confined to such broadcasts as those sponsored by Fleischmann's Yeast, Cocomalt, Ovaltine, and Postum; cereal manufacturers are making aggressive moves in this direction, and lately even Wrigley's has recommended chewing gum for its healthful and beautifying effects.

In *Business Week*, 330 W. 42d St., New York, N. Y. Feb. 9, 1935. 20 cents.

A.P.H.A. Year Book: 1934-1935
—Readers of this section will wish to study the "Resolutions" chapter for possible reminders of emphasis desirable in the months ahead.

Likewise a review of the numerous committee reports may provide valuable background material, especially when we need statements of approved practices or of aims in special fields.

Be sure to check possible uses of the objectives (and their "first fruits") of the A.P.H.A. which correspond closely with the objectives of public health. (We do wish that there was recognition of popular health education

* Please address questions, samples of printed matter, criticism of anything which appears herein, etc., to Evart G. Routzahn, 130 East 22d St., New York, N. Y.

as a large factor in making possible the harvesting of the "first fruits" there listed.)

P.H.E. Section in the Year Book—The Year Book, 1934-1935, record for the Public Health Education Section:

Committee on Fellowship and Membership—William P. Shepard, M.D.

Committee on Administrative Practice—Ira V. Hiscock on Sub-Committees on Record Form, Manual of Public Health Administration, Annual City Health Department Reports, and Relationship of Social Workers to Public Health.

Committee on Professional Education—C. E. Turner, Dr.P.H., Secretary; John Sundwall, M.D. Sub-committee on Training and Qualifications of Health Officers—C. E. Turner, Dr.P.H. Sub-committee on Training of Public Health Educators—C. E. Turner, Dr.P.H., Chairman; John Sundwall, M.D.; William P. Shepard, M.D.; Mary P. Connelly, R.N.; Edna A. Gerken.

Committee on Meetings and Publications—Homer N. Calver. Associate Editors of *Journal*—Evert G. Routzahn. Sub-committee on Scientific Exhibits—Homer N. Calver, Chairman; Bertrand Brown; H. E. Kleinschmidt, M.D.; Evert G. Routzahn.

Committee on Research and Standards—C. E. Turner, Dr.P.H.

Nominating Committee—W. W. Peter, M.D.
Committee on American Museum of Hygiene—Homer N. Calver; Bertrand Brown; Evert G. Routzahn.

Committee of P.H.E. Section on Methods in Health Education—Ira V. Hiscock, Chairman; Homer N. Calver; Mary P. Connelly; Iago Galdston, M.D.; Elizabeth Nickerson; Evert G. Routzahn; William P. Shepard, M.D.; C. E. Turner, Dr.P.H.

What Shall We Call It?—A terminology Committee of the Health Education Section of the American Physical Education Association has tackled a much needed job. The committee has prepared terms and definitions, largely from the angle of school health education.

A report will be presented for action at the annual meeting of the A.P.E.A. in April. The committee, Jesse Feiring Williams, Chairman, includes among

others, Louise Strachan and Anne Whitney.

In anticipation of the final action we give but three of the terms to illustrate what is being done. The term and definition appear in italics; followed by

. . . a paragraph of informal discussion that seeks to amplify the definition, to give the reasons for the decision made, or to indicate more specifically the application or limitation of the term.

I. Health Education is the sum of all experiences which favorably influence habits, attitudes, and knowledge relating to individual, community, and racial health.

Health Education is a general term covering a wide field of human experiences. It includes more than just instruction in health and should be used to designate the broader field.

II. School Health Education is that part of Health Education that takes place in school or through efforts organized and conducted by school personnel.

The child is educated in health in all his experiences that in any way influence favorably his habits, attitudes, and knowledge relating to health, but the experiences he has that emerge from and are identified with school life are those of *School Health Education*.

This aspect of *Health Education* is definitely linked with *Public Health Education* as it operates in the home and community.

III. Public Health Education is that part of Health Education that takes place in home and community.

This phase of *Health Education* operates largely through the efforts of health departments and various semi-public or private agencies interested in promoting health among the people. As a rule the methods used are those of general publicity such as radio, newspapers, distribution of literature, lectures, study groups, conferences etc., but the work done in homes by public health personnel is also *Public Health Education*.

Public Health Education reaches children as well as adults and thus is one kind of experience relating to health.

The public health official who comes into the school to control communicable disease is

in effect a school official and hence this experience of the child may be regarded reasonably as an aspect of *School Health Education*.

Meet "Bill the Driller"—*Ohio Health News* reminds its readers that more drilled-well water supplies are contaminated from above than from below the surface. The *News* quotes from *Johnson's National Driller* what "Bill the Driller" says on the subject:

Fer th' good of our own business as well as th' safety of our customers, us well drillers ought to follow ev'ry reasonable thing that th' health officers, engineers or other people suggest to protect our wells from pollution. I never cut off th' top of a well casin' below ground level if I can help it, an' where I have, I seal th' top around th' pump an' casin' both as tight an' fool-proof as I can. I arrange fer drainage into a gravel fill an' keep a sharp eye against chances fer floodin' from th' surface or sewers.

More paragraphs follow, but the above is enough to suggest that health agencies look up well drillers and "get them educated." Also enough is quoted to emphasize the idea that we try to present health and trade health responsibilities in terms of the different crafts and professions.

Ohio Health News, State Dept. of Health, Columbus. Jan. 1, 1935.

"Exhibit of Food Fads and Fallacies," by H. S. Mitchell, tells of an exhibit of materials about food fads and fallacies as a part of a community education project. The exhibit was shown at a recent meeting of the American Dietetic Association.

Every home economist is aware of the fact that there is much false printed material in circulation in the form of advertisements and magazine and newspaper articles. Samples of such quack publications come to our attention at intervals, but a large collection of such material arranged so that it can easily be read, makes a striking educational exhibit and brings out the point that it is not always a simple matter to choose between the true and the false. Even for a group of dietitians it was necessary to label carefully the false ma-

terial to avoid any chance of misinterpretation. The worst statements or paragraphs were underlined or marked in bright red.

The printed matter was mounted on large black cardboards.

"What about Food Combinations," with a large question mark following it, was the heading on a board which carried samples of some 15 or more articles and tables of foods stating which should or should not be combined. The dire consequences of the wrong combinations designated by one "authority" as likely to produce toxic poisons, by another as leading to the possibility of an explosion, were well worth underlining. Such fads about food combinations have perhaps swept the east and west coasts more than other parts of the country, but in general an intelligent group of people is apparently being won over by these erroneous ideas.

"Is there Supermagic in Minerals?" was the heading for

. . . numerous magazine articles in which some specific mineral was presented as a panacea for many ills. In other instances famous movie stars and other prominent people were pictured and designated as belonging to particular mineral types and requiring specific foods because of these types. Iodized foods were recommended as panaceas for a variety of ailments.

"Short Cuts to Reducing?" introduced

. . . samples of the many advertisements for quick-reducing remedies (the dangers of which are well recognized by any home economist), especially mineral water, salts, and remedies containing dangerous drugs, all recommended by their various advocates.

"Do You Believe Everything You Read?" headed other groups of false advertising and fallacious articles. "The Nutritionist Looks at Food Fads" headed a collection of sound articles, some of which are listed.

In *Journal of Home Economics*, 101 East 20th St., Baltimore, Md., Feb., 1935. 30 cents. In the same issue see editorial on "Food Fads and Fallacies."

Those interested may learn through American Dietetic Association, 25 E. Washington St., Chicago, Ill., if your state has made up an exhibit.

The general idea may be worked out in a variety of ways. The headings suggest a series of articles, a study course, or meeting topics. This approach could be applied beyond the field of food, and even without reference to misleading articles or advertising. The exhibit plan illustrates the possibility of reexamining our material for new angles of presentation.

How the Smiths Learned and Shared—Jean Pinney undertakes to answer "How Much Does the Public Know about Social Hygiene?" And her effective device for showing progress is to tell the story of the Smiths, what they said and what they did, from immediately before the Great War up until today. It is a genuine "success story" for the social hygiene movement, but it presents a convincing moving picture of changing ideas and effective activities. This article with other material in the Jan. and Feb., 1935, issues of *Journal of Social Hygiene*, constitute one of the best annual reports of a national health agency and of a national health movement. Address: 50 West 50th St., New York, N. Y. Each issue, 35 cents.

Using People in Rural Communities—"Utilizing Organized Groups in a County Nursing Program," by A. B. Stoll, might well read "Utilizing Organized Groups in a County Health Program." Read before a Jackson, Miss., conference it is a small city and rural presentation.

From "How to Use Volunteer Help Effectively" we quote:

Going to our card index or notebook, we hunt through it, finding out what special interests we have tabulated among the committee members. Here we have one who has studied typing and can get no work. When we ask her if she is losing her skill and speed, we often find she is worried over just that thing. She will be a rare person if she will not help us with some of our clerical work

and indirectly keep herself in form. She can be taught mimeographing and can assist in preparing the quarterly reports for the central health committee. Others may want to keep up in dictation. Requests sent in to graduates of night school often bring results.

Occasionally, we may find someone who has a special talent for writing who may prepare excellent articles with local interest from authentic information. He also would be responsible for publishing news items concerning the activities of his own committees.

Those who can entertain successfully in their own homes will be interested in planning exhibits, programs, and entertainments for their organization.

Add gradually to your card index another section containing the names of the people whom the health department has helped outstandingly. I recall a story of a health officer who said he had discovered that a child of a lawyer needed glasses badly. The father looked up the director and expressed his appreciation to him and then the father added, "Why, the little fellow has always been that way and we didn't know he couldn't see." When that officer has difficulties, he goes to that man and things mysteriously happen. We have all had experiences like that and we forget about them. But in time of stress such information could be turned over to your health committees and the services we gave, without thought, could come back bearing multiplied results—not to us, but for increased opportunity for service to others.

In *Public Health Nursing*, 50 West 50th St., New York, N. Y. Jan., 1935. 35 cents.

The School Nurse Helps the Teacher—How the school nurse shares in educational work is brought out by E. N. Scramlin in "The School Public Health Nurse a Health Educator." One

important educational contribution of the school nurse should be that of serving as adviser to the teachers. The teaching profession is probably one of the most harassed in the world. However eager a teacher may be, it is humanly impossible for her to keep abreast of all the topics in which she is interested, and almost no field of information changes so rapidly as that of health. Scientific research today renders yesterday's dogma obsolete tomorrow. The nurse may make one of her most valuable contributions that of acting in an advisory capacity to the teachers,

keeping them posted on the best bibliographies, and assisting them in evaluating health books and other sources of health information.

Other specific opportunities are mentioned, and it is emphasized that

In a wider sense the school nurse becomes a teacher and educator with every professional contact she makes, whether it be with student, teacher, or parent. Every physical examination should be done with the coöperation and interest of the student that it may become a teaching situation of value. Every inspection of an ill child and every case of first aid is a learning situation. The nurse who understands will create with every contact a favorable attitude not only toward the medical profession but toward finer ideals and standards of living in the child.

In *Public Health Nursing*, 50 West 50th Street, New York, N. Y. Feb., 1935. 35 cents.

Hygeia, March, 1935—Background and quotable material offered in *Hygeia*, American Medical Assn., 535 N. Dearborn St., Chicago:

Animal experimentation. Mental strain masking as physical disease. Food fads (against generalized hard and fast rules). If you have a lump in your breast. Pneumonia. Massage vs. mauling. Healthgrams. Posture. Slum elimination. Beulah's Bunion (a fable). A.M.A. committee on fish. The house fly. Eye diseases during adolescence. A straight face and straight teeth. How to make health attractive to the child. Tonsils and tact. What to do and what not to do for fever. The medicine men (a puppet play).

Under "School and Health":

The classroom teacher studies the community. Health teaching in March. Solving health education problems. New health books for teachers and pupils.

Hygeia will send a copy free to a teacher or health worker.

Simple Dramatics—"The Medicine Men," by John Finney, is one of the few adaptations of health material for puppet presentation. For children/adults—by children/adults.

"The World's a Stage," by Sophia

Yarnall, tells of a mother's use of costume plays and home "broadcasting" by young children. This project offers possibilities where health stories are available, say to members of parent-teacher groups, and others. Copies of this article or condensed explanations of the idea may be used in testing the project.

Both in *Hygeia*, 535 N. Dearborn St., Chicago, Ill. March, 1935.

England Honors Hamilton's Health Education—The Hamilton, Ont., Public Health Dept. has been honored by having two pieces of health propaganda reproduced in *Mother and Child*, 5, Tavistock Sq., London, W. C. 1, together with this comment:

The Hamilton (Ontario, Canada) board of health has a remarkable gift for keeping its activities "in the news." The *Hamilton Spectator* periodically devotes an entire issue to the question of public health. The latest special health issue is an excellent example of good journalism and sound propaganda.

Education Against Cancer—From "The Present Status of the Educational Campaign Against Cancer" we quote:

It is very human and understandable to attack an obvious condition that announces its own presence. Such efforts should be continued. They are laudable and constructive. These facts, however, should not blind us to the greater problems which call for long-time and general coöperation.

The effort needed to organize and establish a national educational campaign in any phase of public health, is so great that no group or groups care to undertake such a program without a great deal of careful preliminary study. This work has actually formed a considerable part of the society's program during the past 5 years.

It has been necessary first of all for the American Society for the Control of Cancer to establish in its own mind beyond any doubt that certain types of cancer in their early stages are curable. This it has done.

It has next been necessary for some one to study the facilities for treatment and to aid in informing the medical profession of what can be accomplished. This work is being

splendidly performed by the American College of Surgeons, the American Medical Association, and by the various National Radiological Societies.

Having carefully built up a foundation of scientific and medical knowledge concerning the disease itself and the facilities for its treatment, the next step is clear. This consists of the establishment of local organizations which will assume the responsibility and expense of educating the laity to recognize signs and symptoms which may mean cancer and to report those signs and symptoms *immediately* for diagnosis and treatment. This work will form the major activity of the American Society for the Control of Cancer for some years to come.

The Board of Directors of the Society are hard at work on the problem and an important announcement of the future program may shortly be expected.

In *Bulletin*, Am. Society for Control of Cancer, 1250 6th Ave., New York, N. Y. Feb., 1935. 10 cents.

MAGAZINE ARTICLES

"Has Insulin Failed?" by Dr. W. W. Bauer. *American Mercury*, 730 5th Ave., New York, N. Y. Nov., 1934.

"Poison Hunters," by R. Lord. The food and drug staff of Dept. of Agriculture. *Today*, 152 West 42d St., New York, N. Y. Feb. 2, 1935. 10 cents.

NEW

Flashes, State Committee on Tuberculosis and Public Health, S.C.A.A., 105 East 22d St., New York, N. Y. House organ for county and city workers throughout the state. Mimeographed, with two-color printed cover sheet, date and number being mimeographed on the printed sheet.

RADIO

Is it WEAf or W.E.A.F.—as it appears anywhere but in a health agency release or a health publication?

Reported by *Education by Radio* (1201 16th St., N.W., Washington, D. C.), Jan., 1935:

Radio station CKUA, the University of Alberta, Edmonton, Alberta, presented on

Monday, January 7, a program entitled, "Venereal Diseases—Prevention and Control." The speaker was Dr. Harold Orr, director, social hygiene division, Provincial Department of Health. The program was given at 2 p.m. and was presented not only by the University station, but by stations CFAC and CJOC.

Says *Variety*, amusement weekly:

Radio has been guilty of cheapness and tawdriness and phony sentimentality, but it's always been on the side of obedience, reverence, holy wedlock, and spinach. . . . Radio is probably the most sanctified amusement in history.

"Keeping Well," is made up of "the first 100 radio talks broadcast by Baltimore City Health Department and Medical and Chirurgical Faculty of Maryland from Station WBAL." 193 pages; contents and index; list of the Public Instruction Committee of the Faculty. The 100 talks include one monologue and two dialogues.

"A Day in an Emergency Ward," by Dr. J. J. Moorhead, was an effective idea for a broadcast. In this particular instance this was less description and more appeal for support than usually would interest the radio audience. United Hospital Fund, 122 East 22d St., New York, N. Y.

"The Romance of a Hospital," by B. Fingerhood. Explaining some misunderstood aspects of the hospital. *Bulletin*, Am. Hospital Assn., 18 East Division St., Chicago, Ill. Jan., 1935.

"Common Sense and the Child," an English broadcast series included some catching titles:

Running a dinner centre for country school children. Is he growing properly? "Catching" illnesses. Should he have a dose? Aches and pains.

A.M.A. broadcasts are scheduled over N.B.C. at 5 p.m., E.S.T., Tuesdays; over C.B.S., Thursdays at 4:30 p.m. A list of the stations appears in *Hygeia*.

American Medical Assn. broadcasts in March:

Surgery in diabetics. Food and drug law

revisions. White collar hazards. Plans for economic security. Headache. Physical defects. Rickets. This is no April fool.

Baltimore Health Dept. and Medical and Chirurgical Faculty broadcasts:

The health of your child in school. Baltimore's health record for 1934. Oysters. Infected eyes in infants. A day with a public health nurse. City health for a cent and a half (health in city tax dollar). Meningitis. Your heart at fifty. Rheumatic fever and the heart. Some Christmas cautions. The pestilence that walketh in darkness (tuberculosis). What to do until the doctor comes.

Connecticut Dept. of Health broadcasts over WTIC:

Controlling your weight. The laboratory an ally in pneumonia. Health protection in industry pays. Keeping your child well during the winter months. Things are seldom what they seem (problem behavior). Statistics measure progress. Bad news for pneumonia germs. Dividends from public health work. Working environment (occupational disease). Man's struggle for health. Finding defects early. Unusual accidents. Safeguards for public water supplies.

The Hartford, Conn., Tuberculosis and Public Health Society has had a twice weekly radio program: over WTIC in coöperation with Hartford Medical Society; with lay speakers over WDRC on the health activities of various local agencies. Some of the topics:

That fat bugaboo. The hoarse voice. Diagnosis and correction of posture defects. Oral hygiene. Overcoming tuberculosis. Neuritis and neuralgia. Child guidance. The cross-eyed child. Diabetes and tuberculosis. Diet and digestion.

Illinois Dept. of Public Health broadcasts over WCFL:

Enemies 1/8000 inch in length. Health progress in 1934. Shell shock in everyday life. When a fellow needs a friend. Science and human guinea pigs. Fighting foes too small to see.

Illinois Dept. of Public Health broadcasts over WGN:

Mental hygiene faces the newer facts. Crime and the new deal in mental hygiene. Are you superstitious? On the fringe of

silence. The biological miracle of five centuries. Medicine marches on. Hair-raising information. The "white-collar disease."

Minnesota State Medical Assn. broadcasts (Tuesday) over WCCO:

Insomnia. Appendicitis. Problems of the blind. Cancer research.

DATES AHEAD

Among these may be found opportunities for coöperation with other groups; timely angles for newspaper, radio, or public speaking material.

May 1, 1935: May Day—Child Health Day. Write to your State May Day Chairman or to your State Health Dept.

April 27–May 4, 1935: Youth Week. "Designed to include boys and girls from about 10 to 18 years of age." Address National Youth Week Committee, 35 E. Wacker Drive, Chicago, Ill. Wednesday, May 1: Youth's Health Day and Evening at Home.

To stress the responsibility of the family for the welfare of boys and girls and to emphasize the importance of having a sound body to insure a sound mind.

May 11, 1935: American Indian Day. Health implications for boys and girls.

May 12, 1935: Mother's Day. "To make maternity safe" in the country where it is more dangerous to be a mother than almost any other known as "civilized." Address Maternity Center Assn., 1 East 57th St., New York, N. Y.

May 12, 1935: National Hospital Day. A "bulletin of 35 suggestions for its observance" will be supplied by American Hospital Assn., 18 E. Division St., Chicago, Ill. Arrangements have been made for hundreds of addresses, and for broadcasts from over 50 stations.

MOTION PICTURES

American Medical Assn., 535 N. Dearborn St., Chicago, Ill., has prepared a 16mm picture

. . . so that county and state medical societies as well as other organizations might be informed of the nature of the work in the headquarters office. . . . It shows the personnel of the various bureaus and councils of the Association, the executive officers, the members of the Board of Trustees and of the House of Delegates, the composing, printing, binding, addressing and mailing departments, the manuscript editing rooms and the library, and many other activities of the headquarters office. . . . It is planned to add pictures of all the different councils and official bodies so that the film will constitute a true record of the history of the Association at this time. Adequate subtitles explain the nature of the work shown, but the affairs are so complex that space is simply not available in a subtitle to indicate fully the significance of the various activities. The Board of Trustees and the office of the Secretary of the Association will be interested in hearing from county and state medical societies or other bodies that are interested in showing this film.

State Dept. of Health, Albany, N. Y., is using a picture produced by Bureau of Milk Publicity, Dept. of Agriculture and Markets:

Three clowns—Health, Pep, and Strength—demonstrate the advantages of milk. Flashes of actual persons engaged in sports, business and other activities, combined with animated cartoons of elflike characters, cleverly illustrate the importance of milk as a principal source of the food elements essential to proper growth and development of the human body. Pictures of the dairy industry show the sanitary methods essential in each step of the production and distribution of safe milk, from the farmer's pail to the consumer.

A news dispatch is quoted in *Health*, Canadian Social Hygiene Council, 105 Bond St., Toronto, Ont.:

Officials of the Canadian Social Hygiene Council are gratified that the showing of a picture produced by the council provoked a debate in the House of Lords in London on the need for certificates of medical fitness for parties proposing to marry.

The debate was instigated by Lord Kilmaine who mentioned that he had seen the picture, "Damaged Lives," an educational picture dealing with the problem of social disease, produced under the technical direction of Dr. Gordon Bates, General Director of the Canadian Social Hygiene Council.

This picture, according to the council, has

been shown to millions of persons in a large part of the civilized world. Its showings in England were with the full approval of the British health ministry and social hygiene council. It has also been shown in Canada, United States, Australia, New Zealand, Mexico, Argentina, Chile, Brazil, France, and Spain.

MOTION PICTURES IN ENGLAND

A recent motion picture is "Rules for Jim," by National Baby Week Council, 117, Piccadilly, London, W. I. The sound version, 12 minutes; silent, 15 minutes.

"How to Run a Schick Clinic without Tears" pictures clinic methods which have met the fears and doubts of parents, and is the outgrowth of 5 years of successful campaigning by Dr. E. H. T. Nash, Medical Officer of Health, Hounslow, Middlesex, England. The film is being offered for use throughout the kingdom.

A new 16mm film is offered by National Council for Maternity and Child Welfare, 117, Piccadilly, London, W. I., which

. . . represents a mother bathing her baby in her own home. The different scenes illustrate undressing, habit training, bathing, making up the cot, and the activity of a normal healthy infant. This film should make an appeal to many and various audiences, partly on account of its human interest so delightfully illustrated by the activities, cries and smiles of a perfect 2 months old infant, and also on account of the technical accuracy which Sister Kennedy expresses in such a calm, unhurried manner. It will delight and instruct at the same time, and prove of great value to Health Week campaigns, infant welfare centres, women's groups, fathers' councils and to school-girls.

REPORTING

"Activities—1934" is a mimeographed report of Rapides Parish Health Unit, La. Several pages of description and comment; statistics; and illustrated cover—health problems on left, health activities on right. The kraft paper is a bit dark, but then it is "a Louisiana product."

The annual report of Lincoln, Neb., Board of Health is 4 by 9 inches in size, 16 pages and cover. The usual dull appearance of statistical tables seems to be lessened by the narrow pages. Some brief explanatory paragraphs will help the lay reader to get the significance of some of the data.

"Estado de Nuevo Mexico Departamento de Salubridad Publica, El Octavo Informe Bienal, 1933-1934" appears on one cover of a 40 page pamphlet, but turned over the cover reads: "State of New Mexico Bureau of Public Health, Eighth Biennial Report, 1933-1934." The text and *table of contents* appear in both languages.

"Guarding the Health of Baltimore" is an attractive looking pamphlet of 35 pages issued annually by Baltimore Health Dept. A reprint of the Commissioner's Report from the annual report; pleasing blue cover; text on rough finish paper. Illustrated.

"Health unlocks the door to happiness" is the "Health Officer's 1934 Report, Middletown, N. Y." Mimeographed; 15 letter-size pages; illustrated. Tint and weight of paper, quality of mimeographing, the illustrations, and the homely comment place this in the front rank of small city reports. *It has a table of contents.* Report mentions that a Middletown leaflet on diphtheria was reproduced in several cities.

In "Fifty Years of Health Progress in Rochester" the bulletin of Rochester, N. Y., Bureau of Health, makes good use of the historical comparison. The 50 years includes the full period for which Rochester has comparable figures.

Palo Alto, Calif., Health Dept. issues an annual report with an unofficial looking cover, but dignified and pleasing.

A self-indexed annual report of the

Florida Tuberculosis and Health Assn., Jacksonville, is small enough for correspondence enclosure and pleasing enough for popular reading. Each of 8 leaves is a half inch wider than the preceding one so that the "contents" may be read from left to right on the unopened pamphlet. Copy for 3 cents.

"Ten Years at Bellevue-Yorkville: An Experiment in Health Center Administration" is the report of a meeting which practically marked the close of the last of the group of health demonstrations in New York State. The project continues as a municipal health center at 325 East 38th St. Mention is made of 3,000,000 pamphlets having been distributed in the district.

Students Study at a Sanatorium—High school seniors are being given first hand information about tuberculosis prevention and treatment as illustrated by the equipment and practices of a tuberculosis sanatorium under the sponsorship of the St. Louis Tuberculosis and Health Society.

Groups are taken through Robert Koch Sanatorium with explanations and demonstrations of equipment for diagnosis and treatment. A question and answer session follows in the auditorium of the hospital, together with a motion picture illustrating the main points to understand about tuberculosis.

According to a check-up of the students who have attended these sessions it is reported that "100 per cent felt that they had definitely benefitted by the classes." A general finding is that fear has been dispelled and interest become more active among these students. Some local education and health authorities have suggested that the plan be extended to lower grades.

BOOKS AND REPORTS

A REVIEW OF SELECTED BOOKS OF INTEREST TO PUBLIC HEALTH WORKERS

MAZŮCK P. RAVENEL, M.D.

FOR several years we have omitted our annual review of books on public health, partly because there were fewer received and partly on account of financial conditions. During 1934 there have been a number of excellent books and it has seemed wise to renew the custom of an annual review. This covers books reviewed in our *Journal* in 1934 as well as some which have been received but reviews of which have not yet been published, though some of them have been written. We have also followed the reviews in a number of other journals, in England and this country. Under the head "Miscellaneous" will be found a number of titles which might very well be classed under other heads. We have avoided German and French books which have not been translated and published either in England or this country. One French book is of such importance, however, that we have included it.

Perhaps the workers in industrial hygiene have been more active than other groups. There have been many incidents which have brought the problems of industry strikingly before the public. There have been many new chemicals, some of which are poisonous, brought into use in various lines of work, which have raised new questions and led to suits for compensation. Among important books on this subject we may mention *The Human Problems of an Industrial Civilization*, by Elton Mayo, Macmillan. This is made up of the Lowell Lectures for 1933, and will interest all who have to do with employee problems. There is no adverse criticism to be made of *Science of Work*,

by Morris S. Viteles, Norton. It covers a large field. The selections are well made and the illustrative material is concrete and to the point. It is obviously written for non-technical readers, but is systematic and well done. *Industrial Health Service*, by L. D. Bristol, Lea & Febiger, gives the first appraisal forms, (1) for smaller industries; (2) for personnel and industrial relations services, though they were considered in the section on Industrial Hygiene of the Association, and a suggested form presented to our Committee on Standard Practices in 1932. *Industrial Toxicology*, by Alice Hamilton, Harper, is an excellently organized, comprehensive, and terse book, and is especially timely on account of the many new chemicals used in various industries, especially dyeing, rubber manufacture, metal plating, etc.

Few subjects have been less understood than heating and ventilation, though of great importance, since workers in many lines are exposed to extensive ranges in moisture and temperature. *The Principles of Heating and Ventilation*, by H. M. Vernon, Edwin Arnold & Co., has been described as "a source of welcome enlightenment indeed." An outstanding book is *Industrial Maladies*, by the late Sir Thomas M. Legge, Oxford Medical Publications. Unfortunately, this well known student of industrial diseases has passed away. Studies of much significance are *Occupation and Health*, Vol. II, Letters I to Z, International Labour Office; and *Death Rates by Occupation* by Jessamine S. Whitney,

National Tuberculosis Association. The various types of pneumoconiosis are among the more urgent problems in industrial hygiene. Some firms have been forced to the wall by claims for damages. Abrasives are much used. A striking instance of injurious work is that of a tunnel bored through rock containing much quartz. Physicians, engineers and others are called on to testify in such cases and to arbitrate and adjust claims. For them, such a book as *The Pneumoconiosis Bibliography and Laws*, by Davis, Salmonsen and Earlywine, *Industrial Medicine*, is of much value. The tunnel incident, which led to a number of suits, brought out *Symposium on Silicosis*, by Trudeau School of Tuberculosis, Employers' Mutuals, Wausau, Wis., which is indispensable to those interested in the silicosis question.

The importance of the nursing profession and especially of the public health nurse is coming each year more and more to the fore. Among the books on this subject we will mention *Survey to Public Health Nursing*, by N.O.P.H.N., Commonwealth Fund. It will be seen that this is authoritative, having been handled by the organization devoted to public health nursing. Interesting and valuable is *Nursing History*, by Minnie Goodnow, Saunders, which is unusual in its type and scope, being very human and showing the trend of the care of the sick up through the ages, and mentioning even the care of animals in some conditions. Among special subjects are *Obstetrical Nursing*, by Carolyn Van Blarcom, Macmillan; *Pediatric Nursing*, by Gladys Sellew, 3rd ed., Saunders; and *Keeping Campers Fit: The Theory and Practice of Camp Nursing*, by Elena E. Williams, Dutton. The latter is a rather unusual book, useful on account of the many summer camps in various parts of the country. It discusses the types of cases likely to be met with by

the camp nurse, and gives first aid for them. The author regards these camps as a useful field for practice.

America has made a bad showing on the score of maternal mortality, two especially useful studies of which have appeared during the year. *Maternal Mortality in New York City*, by Committee on Public Health Relations, New York Academy of Medicine, Commonwealth Fund, is a timely and valuable study, applicable especially to New York City, but containing much material of general application. *Maternal Mortality and Morbidity*, by J. M. Munro Kerr, Wood, is a most complete and exhaustive study, and while made on material gathered in England, Scotland, and Wales, the basic factors are comparable with those in the United States.

History: Two most interesting books, *Chinese Medicine*, by William R. Morse, Hoeber; and *Japanese Medicine*, by Y. Fujikawa, Hoeber, belonging to the series, "Clio Medica," edited by E. B. Krumbhaar, have appeared. They cover the story in a remarkably succinct manner from ancient times up to the present. Several books of a more or less general type giving much medical history have appeared. Perhaps the best of these is *Medicine: A Voyage of Discovery*, by Josef Lobel, Farrar & Rinehart. It is an exaltation of medicine, most interesting and correct for the most part. A book with an engaging title, *The Great Doctors*, by Henry E. Sigerist, Norton, should be mentioned, which in spite of inaccuracies in statement as well as in implication, contains useful material. Bacteriology, on which modern public health is largely founded, has been greatly aided through the invention of the Abbe condenser and the use of aniline dyes. The Biological Stain Commission, with headquarters at Geneva, N. Y., has put laboratory men of all kinds in its debt, which is now

increased by *The History of Staining*, by H. J. Conn, a most valuable contribution.

Allied to medical history is *Great Men of Science*, by Philipp Lenard, Macmillan, which contains material concerning men of science which should be more or less familiar to all educated people.

In this group might well be classed some notable biographies and autobiographies. *Lord Lister: The Discoverer of Antiseptic Surgery*, by C. J. S. Thompson, John Bale, Sons and Danielsson, is a short and excellent picture, with many facts drawn from the classic biography by Sir Rickman John Godlee. *Benjamin Rush*, by Nathan G. Goodman, University of Pennsylvania Press, is the first biography ever written of Benjamin Rush, known as "The American Sydenham," in spite of the many articles and books written on certain phases of his career. It is excellently done and should be in the library of every physician in the United States. *The Joy of Living*, by Franklin H. Martin, Doubleday, is by one of the most efficient and active medical organizers in this country or any other. He has lived through a period characterized by great advances along practically all lines, and gives an interesting account of his experiences in pushing the interests of the medical profession forward. *A Soldier in Science*, by Bailey K. Ashford, William Morrow & Co., appeared a short time before the author's death. It is delightfully written, and though we cannot agree with all the author claims, there is no question that his work had a profound influence on health in the tropics and on the study of tropical disease.

Health officers particularly should know a great deal about veterinary medicine. *Manual of Veterinary Bacteriology*, 2nd ed., by Raymond L. Kelser, Williams & Wilkins, is a book by a man whose experience in the Army

has led to constant associations with medical men as well as with biologists, and the practical application of scientific knowledge. There is a chapter on protozoa by Charles F. Craig. *The Biology of Bacteriology*, by Arthur T. Henrici, D. C. Heath & Co., is a useful book, written from an unusual angle. New editions which deserve mention are *Pathogenic Microorganisms*, by William H. Park and Anna W. Williams, Lea & Febiger, 10th ed.; *Bergey's Manual of Determinative Bacteriology*, Williams & Wilkins, 4th ed. *A Text-Book of Bacteriology*, by Hans Zinsser and S. Bayne-Jones, Appleton-Century, though called the 7th edition of the book by Hiss and Zinsser, is practically a new work, considerably enlarged and brought much more up to date.

Under this head we must mention *Text-Book of Meat Inspection*, by Robert V. Ostertag. Translated by C. P. Marshall, and edited by T. Dunlop Young, Alex Eger. This is an entirely new book by a master. The translation is excellently done and both the English and American editions have been edited by a veterinarian. In the appendices are given the laws regarding slaughter, handling, curing, and sale of meats in Germany, England, Australia, and America. It should be in the hands of all health officers though written especially for veterinary physicians, many of whom hold positions in the inspection service. *Text-Book of Meat Hygiene*, by Richard Edelmann, 6th ed., translated by John H. Mohler and Adolph Einhorn, Lea & Febiger—This translation of the 6th German edition has been well done. It is a smaller book than that by Ostertag, and excellent in every respect.

Outline of Immunity, by W. W. C. Topley, Wood, is a new book which shows a mastery of the intricate subject of which it treats. The facts and theories are clearly stated. The importance of protozoan diseases need not

be emphasized, since epidemics during the past 2 years have done that for us. We welcome that standard work *Biology of the Protozoa*, by Gary N. Calkins, 2nd ed., Lea & Febiger. This second edition of a well known book contains a new chapter on parasitism and disease, adding much to its practical value.

Two excellent books have appeared on physical education. *Safety in Physical Education in Secondary Schools*, by Frank S. Lloyd, National Bureau of Casualty and Surety Underwriters, New York, is extremely valuable, especially for those responsible for secondary school activities. The second is *Administration of Health and Physical Education*, by Jesse Feiring Williams and Clifford Lee Brownell, Saunders. Everything written by Dr. Williams is well worth reading. This book will be especially useful to heads of physical education departments, and we must commend the idea of the authors in stressing physical education as a health measure.

Nutrition has, as usual, received considerable attention. Everyone will be glad to see a revised edition of the well known book, *The Foundations of Nutrition*, by Mary Swartz Rose, Macmillan, "written for those who wish to live more intelligently." Two books by H. C. Sherman came to hand during the year. *Food Products*, Macmillan, is a 3rd edition so completely rewritten as to be practically a new book. It gives in appendices the Food and Drugs Acts, meat inspection and regulation, mineral content of foods, and vitamins in foods. The second is an entirely new book, *Food and Health*, Macmillan. Needless to say, all that Professor Sherman states is authoritative, and these two books with that by Mrs. Rose give all that the average reader could need on the subject.

Diet and the Teeth, by May Mellanby, His Majesty's Stationery Office, is Part III of a study which has

been intensively carried on for 17 years. This part is devoted especially to study on humans.

Food-Borne Infections and Intoxications, by F. W. Tanner, Twin City Printing Co., is an elaborate study of the subjects included in the title. It is of especial value to administrators, domestic science teachers and laboratory men, though all physicians are of necessity interested in the subject. In 1932, a book, *Alcohol and Man*, Macmillan, by 22 authors, was issued under the editorship of Haven Emerson. A smaller book, *Alcohol: Its Effects on Man*, by Haven Emerson, Appleton-Century, is designed for school teachers, high school and college students. Theoretically, prohibition having been repealed, it should be of more use than before.

A number of books on childhood and adolescence have appeared, among which we may mention *The Century Childhood Library*, edited by John E. Anderson, Appleton-Century. There are three volumes, all of which are good. *Healthy Childhood*, by Harold C. Stuart, Appleton-Century, 3rd volume of the series, can be recommended without reservation. It is in many ways the most complete book available on the physical aspects of child hygiene intended for lay readers. *The Road to Adolescence*, by Joseph Garland, Harvard University Press, "deserves wide reading. Helpful in making children of best material and fitting them for life in body and mind." An interesting study is *Idleness and the Health of a Neighborhood*, by Gwendolyn Hughes Berry, New York Association for Improving the Condition of the Poor. This is a social study of the Mulberry Street district, which substantiates the belief that unemployment affects injuriously the health. No correlation was found between unemployment and illness in preschool children. Other publications which will

prove useful and are considered outstanding by some specialists are: *Healthy Babies are Happy Babies*, by Josephine Hemenway Kenyon, Little, Brown; *The Child; His Origin, Development and Care*, by Florence Brown Sherbon, McGraw-Hill; and *Mental Hygiene of the School Child*, by Percival M. Symonds, Macmillan.

A number of books on practice have appeared. It is a temptation to review some of these, since in all contagious diseases, proper care is one of the safeguards against spread.

Miscellaneous: *The Modern Treatment of Syphilis*, by Joseph Earle Moore, Thomas, is an especially good book, which deals also with public health aspects. While we avoid books on treatment, we mention this because the treatment of syphilis is essentially a part of its control. *Contagious Diseases*, by W. W. Bauer, Knopf, is designed for lay readers. *La Lèpre*, by E. Jeanselme, Paris, G. Goin et cie, has not been translated as far as we are aware. It is the one book in a foreign language which we mention, and we are doing this on account of its importance. It should be in all libraries. *Nervous Breakdown*, by W. Beran, Farrar & Rinehart, is especially timely on account of the depression. It is an interesting treatment of a misunderstood subject, with prevention stressed. The Milroy Lectures for 1932, with additions, are presented in *Diphtheria; Past and Present*, by J. Graham Forbes, John Bale, sons & Danielsson. It is an excellent and voluminous treatise, and though the material is drawn chiefly from England, the facts are generally applicable. *The Eugenic Predicament*, by S. J. Holmes, Harcourt, Brace, is authoritative and interesting, but pessimistic. *The Teaching of Preventive Medicine in Europe*, by Carl Prausnitz, Oxford University Press, contains the Heath-Clark Lectures for 1932, based on personal observations and documents from the

Health Section of the League of Nations.

Two especially interesting books are *The Windows on Henry Street*, by Lillian Wald, Little, Brown; and *A Review of Public Health Realities*, Commonwealth Fund. The first is practically a continuation of Miss Wald's first book, *The House on Henry Street*, from 1915 to date. It is most interesting, and though not an autobiography, gives a good picture of Miss Wald and her remarkable work. The latter, by Dr. Chapin, might well have been put under history. It consists of 16 papers selected from 133 by him. Eight of these were given before the A.P.H.A. or published in its *Journal*. We need hardly add that Dr. Chapin is the outstanding city health officer of the United States, if not of the world. The issue of this book was a labor of love in honor of him.

Red Medicine, by Sir Arthur Newsholme and John Kingsbury, Doubleday-Doran, is the story of a trip taken during the summer by the authors. It has been severely criticised on the ground that neither of the authors spoke Russian, and they were shown what the Soviets wanted them to see. However, it is an interesting picture and well worth reading. Of *Chronic Illness in New York City*, by Mary C. Jarrett, Columbia University Press, Professor Boas says: "The first carefully considered review and interpretation of the many aspects of chronic disease, grounded on an adequate factual basis." It is a voluminous study and much of the material is generally applicable. *Blindness and the Blind in the United States*, by Harry Best, Macmillan, is a detailed and comprehensive study, considering among other things, prevention, and the provision made for the blind and their children. *The Physiological Effects of Radiant Energy*, by Henry Laurens, Chemical Catalogue Co., is a masterly and authoritative book, useful chiefly as a text, being too technical.

for the average reader. However, considering the various uses which are being made of radiant energy at the present time, and the necessary exposure of many workers to such influences, it is timely.

Somewhat apart from our subject is a most notable publication, the second edition of *Webster's Unabridged Dictionary*, a monumental work. For years Webster has been the standard of this *Journal* on spelling, pronunciation, usage and meaning of words. It is an indispensable aid to an editor or writer. It is published by G. & C. Merriam Co.

This year is the 150th anniversary of the founding of the publishing house now known as Lea & Febiger. During all these years it has remained in the hands of the descendants of Mathew Carey, its founder. For many years it has been exclusively a medical publishing house. In 1820, the journal now known as *The American Journal of the Medical Sciences*, was founded, "with one exception, the oldest medical periodical in the English language." Since 1859, it has been the publisher of *Gray's Anatomy*. Public health as well as medicine in general owes much to this house, which has always maintained the highest standards. The story of the house is told in *One Hundred and Fifty Years of Publishing, 1785-1935*, distributed free by Lea & Febiger, Philadelphia.

Industrial Maladies—By Sir Thomas Legge, Late H. M. Senior Medical Inspector of Factories and Medical Advisor to the Trades Union Congress. New York: Oxford University Press, 1934. 234 pp. Price, \$4.25.

Dr. Legge's final work was completed by his successor in the office of Medical Inspector of Factories, Dr. S. A. Henry, to whom he left the task of editing. Dr. Legge died on May 7, 1932, at the age of 69. Dr. Henry has prefaced

the book with several pages upon the biography, publications, chief attainments and connections of the author. These review the life of a well trained specialist (Oxford, St. Bartholomew's, and Cambridge) who was the first Senior Medical Inspector appointed, and who served in that capacity from 1898 to 1926.

In a methodical manner, the present work takes up the notification (reporting) of industrial disease and poisoning, followed by a chapter on compensation. Then follow in order chapters on industrial diseases caused by bacilli; poisoning by lead, phosphorus and mercury, arsenic, other metals or their compounds, benzene and its compounds, other organic compounds, and other fumes and gases. Industrial dermatoses and eczema, cancer due to pitch, tar, paraffin, and mineral oil, pulmonary disease due to dust, and other industrial diseases—particularly the neuroses, the special senses, and compressed-air-illness, complete the specific and technical discussion.

The final chapter is devoted to health and welfare conditions in factories and workshops, and the book ends with a list of the books and publications of the author (1893 and 1932), and an adequate index. There are 2 color plates, 11 excellent half-tones, 36 tables and 14 charts or graphs. Table 8 is a large infold giving the statistics of compensation from 1908 to 1931 inclusive, and arranged according to the list of 37 compensable afflictions now scheduled for the British Isles.

The reviewer has critically examined many sections of the work and is duly impressed with the vast amount of knowledge and practical experience contained, as well as with the feeling that he is reading a master. While most of the work narrates the author's own experiences and opinions, he has not been hesitant with acknowledgments to others, and citations, which are frequent,

occur at the bottom of the reading page—a decided advantage.

Dr. Legge's familiarity with German—and it should not be forgotten that it was he who translated Rambousek's *Industrial Poisoning* (1913)—brings this phase of Continental European progress to the fore.

Evidently parts of the book have been edited as dictated so that involved statements occasionally occur, as on pages 55 and 57. However, Dr. Henry must be credited with an excellent posthumous editing of a work the context of which he altered as little as possible.

No doubt the work will be found the most adequate for current interest of any from the author's pen and a chief authority under its title. While the total pages are but 234, the printing set-up is compact, albeit easy to read, and the different subjects are commensurably treated in a well bound, handy volume.

The terminology, while medical, is easily within the grasp of the intelligent lay reader and should place the work upon the shelves of industrial, official, and educational libraries, as well as with individuals in several professions where industrial maladies are involved.

EMERY R. HAYHURST

An Introduction to Sex Education
—By Winifred V. Richmond, Ph.D.
New York: Farrar & Rinehart.
312 pp. Price, \$2.50.

Dr. Richmond modestly entitles this book "An Introduction to Sex Education," but it offers a broad consideration of the subject as detailed in a series of lectures given to the nurses in the Training School of St. Elizabeths Hospital. The excellent content spreads far beyond the classroom and makes an appeal to the physician or general reader who is anxious to secure a summary of the biology, history, and psychology of sex.

Public health officials, as a rule, take comparatively little cognizance of sex save in terms of venereal diseases. They give little thought to the mental illnesses that are outgrowths of sexual ideas and practices. They spend little time in discussing the problems of masturbation or contraception. From their writings and enactments one would not learn that sex and public health have any common factors. There can be no doubt that the numerous sex problems of today preserve part of the continuity of man's development. Sex is and always has been regarded as a driving force involving erotic pleasure as well as biologic purpose, and dynamically determining vital statistics.

The author senses sex itself as a primary factor, entering at all ages into man's physical, social, and religious organization, although still requiring more careful data for scientific evaluation. Public health officials should begin to sense people in terms of what they are, what they do, and how they are influenced by psychological situations, attitudes, precepts and practices originating in or relating to the sexual impulse. Personality cannot be understood without an appreciation of what it derives from the basic sexual urge—public health cannot ignore the personality.

Public health officials should be particularly interested in the discussions of the problems of sex which involve, not merely fears, perversions and prostitution, but include the sexual factors that break down marriage, promote sterility, or are caught up in the numerous individual and social difficulties bound up in venereal diseases.

No public health official of the present day can deny, even though he ignore, the part that sex plays in the declining birth rate, the rising divorce rate, the spread of contraceptive information, and the establishment of birth control clinics, the emphasis upon a eugenic

program, the control of prostitution, the prophylaxis and control of venereal diseases, the increase of neuroses and psychoses in which sexual problems are involved.

While this book is not written from the standpoint of public health, its pages are crammed with public health implications which should be noted approvingly. The scientific approach to the broad problems of public health must recognize the sexual factor. A thoughtful perusal of this book should lead to more constructive thinking among public health officials—but will it?

IRA S. WILE

Food and Health—By Henry C. Sherman. *New York: Macmillan, 1934.* 296 pp. Price, \$2.50.

No well informed person asks why a book was written, if Sherman is the author, but an excerpt from the preface best explains the purpose of this particular one:

Because the writer, having devoted intensive and extensive study over a fairly long time to the sanitary, the economic, and the nutritional aspects of the food problem, believes that it is now possible to summarize the essentials of all three aspects in a sufficiently coordinated way to guide the reader to well balanced judgments in the daily choice and use of food

The main body of the book is a summary of the conclusions, as applied to man, that may be drawn from the more recent studies on nutrition. The topics considered may be classified under the four types of metabolism—energy, protein, mineral, and vitamins. The knowledge we have of these subjects was gained by innumerable individual studies, limited almost entirely to the experimental point of view. It is the task of *Food and Health* to correlate the conclusions that may be drawn from these studies so they may find immediate application in dietetic practice. In large measure the correlation is accomplished by the difficult task of quantita-

tive interpretation. As examples of the wide range of subject matter one may find height-weight tables; the number of calories that must be eliminated from the diet to reduce the weight by 1 pound per week; the daily protein requirement; the daily phosphorus requirement; the kind and amount of food required to supply the optimum amount of vitamin A. One of the important contributions of the author is the emphasis placed on the distinction between passable health and buoyant health, between absence of disease and positive health.

The appendices, pp. 207–259, will be exceedingly helpful to workers in various fields of human nutrition. These include: Nutritional Calories in Common Servings and Commercial Units of Typical Foods; Foods as Sources of Protein and Mineral Elements; Foods as Sources of Vitamins; Illustrative Records of Meals. Those interested in the original literature will find the Selected Bibliography very useful, and there is a carefully prepared index.

Another excerpt from the preface indicates the type of audience this book should reach:

We here attempt to show how the benefits of the newer knowledge may be had without either the restrictions or the fussiness that the term diet too often implies.

This audience might well include that section of the general public which is willing to read an informative book, and all those who have a personal or professional interest in public health.

There is so little in this book that could lead to controversy that the reviewer has some hesitancy in mentioning even one point on which there may be a difference of opinion:

It is partly for this reason that meat should be eaten sparingly, and when eaten should always be well chewed . . . in the hope that its putrefactive bacteria will be largely killed by the gastric juice.

The reviewer believes the average reader will interpret the word *sparingly* much more narrowly than would a representative group of even our most eminent physiologists.

The printing and make-up are excellent.

ALBERT G. HOGAN

Skin Deep: The Truth About Beauty Aids—Safe and Harmful—*By M. C. Phillips. New York: Vanguard Press, 1934. 254 pp. Price, \$2.00.*

No competent health official needs to be informed that much of the modern beauty business is a racket. Gullible women are and probably always will be the prey of mercenary vendors of costly and sometimes dangerous cosmetics, unguents, astringents, lotions, and other aromatic chemicals that are flamboyantly, extravagantly, and often erroneously advertised as positive aids to the attainment of female pulchritude.

This book purports to enlighten the public as to the true nature and the frequently insignificant manufacturing cost of many highly touted and expensive aids to human charm. On the whole, it accomplishes this commendable purpose, but like so much of the material emanating from Consumers' Research, the book tends to be more sensational than scientific, and it is written in the blatant and rather supercilious manner that seems to characterize all of the publications of this self-appointed and somewhat unreliable guardian of the welfare of the ultimate consumer.

In its various chapters, this book presents interesting and useful discussions of face powders and cold creams, hand lotions and so-called hair restorers and removers, lipsticks and rouge, deodorants and sunburn remedies, reducing nostrums and similar bunk. One chapter, devoted to diet, contains some weird alleged facts worthy of any faddist. It is unfortunate that such fatuous statements as that salads should be used

only occasionally, "*if at all*"; that there are hazards involved in the use of cod liver oil; that milk is over-rated as a food for adults; that glucose is an undesirable form of sugar; and that fruits have little value, should appear in any presumably reputable and authoritative text. Such poppycock is still poppycock, whether it occurs in advertising copy or between the covers of a book.

This treatise, boldly naming names, not only of falsely advertised and occasionally worthless preparations, but also of supposedly decent magazines that carry their advertising, will undoubtedly be popular, and deservedly so. Despite its defects, the book contains material of general interest and value. If it helps to bring about some reforms in trade practices, and aids in promoting better legal control of cosmetics, it will have served a useful purpose. The reader will do well, however, to omit the chapter on diet and turn to Sherman, Rose, McCollum, or some other real authority for authentic information on this important topic.

JAMES A. TOBEY

Clinical Laboratory Diagnosis—*By Pauline S. Dimmitt, Ph.G. Philadelphia: Davis, 1934. 156 pp. Price, \$2.00.*

This book is merely a running outline of the essential steps necessary in the performance of a wide variety of clinical laboratory tests. In fact, it is designed for the teaching of brief and probably inadequate courses in laboratory technic to internes and medical technicians. It fails to include any basic theoretical groundwork and proceeds entirely by rule of thumb. It will be found of little value to the worker in a public health laboratory since it is woefully weak in the exposition of those tests routinely applied in public health work.

EARLE K. BORMAN

The Life of Sir Robert Jones—By Frederick Watson. Baltimore: Wood, 1934. 318 pp. Price, \$3.75.

As with all men, the career of Robert Jones was the result of a combination of circumstances and personal qualities which had never occurred before and never will again. The account of his career, written by his son-in-law, reads like a romance and is, in fact, far more interesting than most of the fiction which is being put out at the present time.

Born in 1857, the son of a London journalist, Robert Jones was aided in getting a medical education by an uncle, Hugh Owen Thomas. Thomas was an eccentric genius, but an exceptionally well trained and successful orthopedist of Liverpool, the son of a celebrated bone-setter.

After his graduation in medicine, young Jones practised with Thomas for a time and then set out for himself. In 1888, at the age of 31, he was made Surgeon Superintendent of the Manchester Ship Canal, and put in charge of the health, surgical work, and hospitals required for the 20,000 laborers and their families located along the route of the canal during the 8 years of its construction. Here he gained invaluable experience, especially in emergency surgical work.

Jones was a rapid as well as a skillful operator. On the occasion of a visit to Liverpool by the American College of Surgeons in 1914, he carried out a program of 52 operations in the time ordinarily taken by Americans for 5. It was nothing unusual for him to see 250 patients in a day.

Dr. William Mayo said that Jones was one of the very greatest surgeons he had ever met. Lord Moynihan said:

As an operator he is among the greatest. His technic is flawless, yet simple. His movements show the closest familiarity with every detail of the structural and functional anatomy

of the part and are of the highest excellence in craftsmanship.

His manipulation of a limb might be a demonstration of the immense power which a man of great strength can apply almost ruthlessly when the occasion demands it, or of the most exquisitely gentle and tender caress when only a slight touch is needed. The most stubborn deformity seems by degrees to become subservient to his will, the most obstinate fracture slips nimbly into alignment.

Under Jones's care, cures resulted in a large number of cases which were formerly treated for months and years by orthopedic apparatus, often with unsatisfactory results. Although a skillful surgeon, he was loath to operate unless necessary. He advocated continued care and follow-up until the patient was cured, although this might take a long time. Jones shortened the time for the patients by providing technical occupations for them and substituting an air of cheerfulness in his hospitals for the atmosphere of despondency and gloom of earlier days.

At the outbreak of the World War, Jones placed his services at the disposal of his country and succeeded in obtaining a wide acceptance of his methods in the field and in the hospitals at home. Through his efforts many large special hospitals were established with the object of restoring injured limbs as far as possible and teaching the patients useful occupations suited to them. His contributions to his science place countless persons in his debt who never heard his name.

In later life the prevention as well as the cure of deformities in children claimed much of Jones's attention, and through his efforts centers for the examination and treatment of the youth of the land were established all over England. Rickets and tuberculosis being frequent causes of deformity, he became a crusader for better housing and purer milk supplies.

Jones fought valiantly for the ac-

ceptance of the principles and methods which he knew to be right. He wrote many articles and books, some of which were promptly recognized by the medical profession as marking an advance in the science of orthopedics and all of which were authoritative.

Honors came to him thick and fast. He was created a Major General, was knighted, and received recognition from a number of European institutions and governments. Yale, Harvard, McGill, and Smith conferred degrees upon him. From the United States he received the Distinguished Service Medal.

Death came to him at the age of 76. His remains lie in the cathedral at Liverpool.

GEORGE A. SOPER

Birth Control, Its Use and Misuse—

By Dorothy Dunbar Bromley. *New York: Harper, 1934.* 304 pp. Price, \$2.50.

Nothing better on the use and misuse of modern medical knowledge of contraceptive procedures has appeared in good English from the hand of any non-medical author.

Here we have accuracy and readability in a text addressed to the general public and free from cant, propaganda, or any form of intellectual dishonesty.

There is obvious sincerity of purpose, a thorough understanding of the subject, a gift at simple description, and a degree of common sense and decency in every chapter.

A topic, banned by federal law as obscene since 1873, taboo by religious edicts until recently, feared by physicians from lack of professional education in it, ignored by our health officers, made complex and costly by commercial charlatans, appears simple and clean in the words of this author.

The marvel is that legislators of states and the Nation can so long linger in the dark doubts of other generations in their official attitudes. Some generous social angel might illuminate their

minds by a gift of this book to the wife of each married legislator now in office..

It is certainly to be hoped that we may swiftly follow the example of England, Germany, Holland, and the Scandinavian countries, by including marriage counselling, or merely birth control advice, among the functions of maternal health centers of local health departments, with this little book as a sort of lay *vade mecum*.

HAVEN EMERSON

Handbook of Chemistry and Physics—*Compiled and edited by Norbert A. Lange, Ph.D. Sandusky, O.: Handbook Publishers, Inc., 1934.* 1265 pp. and an appendix of 248 pp. of mathematical talks and formulae.. Price, \$6.00.

This is the most complete chemical handbook which has as yet come to the attention of this reviewer. It should be of value as a source of chemical, physical, and mathematical data not only to the chemist and chemical engineer but also to the public health laboratory worker.

In addition to the usual tables of chemical and physical constants and factors there is included a wealth of information on subjects which are of interest to the worker in the field of public health. Among such material may be found tables on composition of foods, the vitamins, composition of milk, ice cream ingredients, milk solids, lactometer corrections, typical water analyses, drinking water standards, water softening formulae, and algae.

The list of trade names of chemicals with the corresponding synonyms and formulae and the table of hazardous chemicals, giving usual methods of shipping, storage, and common hazards are well worth mentioning.

The section devoted to hydrogen ion determinations is unusually complete. The arrangement of the table of gravimetric factors is a most practical one.

and the table of conversion factors shows not only a sensible alphabetic arrangement of units, but is unusual in its completeness. Considerable engineering information relating to heating, ventilating and hydraulics has been included. A list of definitions of pharmaceutical preparations and therapeutic terms has been added to the usual list of definitions of chemical terms.

To the worker without ready access to various chemical, physical, engineering, and mathematical tables this handbook is to be recommended.

CARYL C. CARSON

Swimming Bath Water Purification

—By *Wilkinson and Forty*. (2nd ed.) London: *Contractors' Record, Ltd.*, 1934. 262 pp. Price, \$3.75.

No American book compares favorably with this volume in covering its subject. The best British practice and objectives are seen, as condensed in this most practical exposition, to be so like ours that the book has a usefulness for operators, managements, and officials charged with sanitary supervision of our indoor and outdoor pools.

The cautious treatment of the relationship of pools to disease merits perusal. Sanitary expediencies and controls are emphasized throughout. Routine operating tests are fully explained and a good round basis for comprehending the full significance of each step of purification is made clear for the layman.

The workings are minutely described for not only the recirculation, filtration, and chlorination devices which are essentially standard for both countries, but descriptions are given of chloramine, ultra-violet ray, Electro-Katadyn, and automatic "Photochlortrol" chlorination equipment, also automatic "Chlortest" free chlorine tester, and commercial manual testing equipment for turbidity, free chlorine, and alkalinity.

Standards include the dictum that the bacteriological content of the water should approximate that of drinking water and that free chlorine should be maintained continuously between 0.2 and 0.5 p.p.m., preferably toward the higher limit, in which case there is normally no need of further routine testing. Chloramine sterilization is given prominence but no great emphasis is given to its slower action than chlorine. The reviewer is not ready to concur unreservedly in the statement that "There is now general agreement that the most efficient, convenient, and generally satisfactory method of continuous chlorination of re-circulated swimming bath water is by means of chlorine gas which is capable of being administered at an unvarying standard of strength and potency, *continuously*, in accurately dispensed quantity, and under *perfect* and instantaneous control" (Reviewer's italics). The incomplete concurrence arises from the desire not to discourage any promising development of application of hypochlorites.

The book is excellently printed and illustrated, with an abundance of diagrams and photographs of equipment.

CHARLES L. POOL

The Vitamin B Requirement of Man

—By *George R. Cowgill*. New Haven: *Yale University Press*, for *Yale Institute of Human Relations*, 1934. 261 pp. Price, \$4.00.

This is a scholarly report on extensive experimental, mathematical, and historical researches on vitamin B and beriberi, conducted by the author and his associates at Yale University during a decade.

Since beriberi is essentially a public health problem, this book, which clarifies the underlying issues and makes important contributions to the control of this disease, will be of particular interest to readers of this *Journal*. The

broad scope of this book is indicated by the following highly condensed chapter headings:

The problem; discussion of beriberi, its incidence in various countries and times; critique of animal experiments; experiments on pigeons, dogs, rats, mice; comparison of data yielded by different species; mathematical formulae relating vitamin requirements to body weight within species and between species with extrapolations to humans; the influence of energy metabolism (exercise, hyperthyroidism, etc.) on vitamin B needs; vitamin B contents and vitamin to energy ratios of different foods; comparisons of author's vitamin B units with published units and results; vitamin B content in diets not associated with beriberi; sex and age incidence of beriberi; explanation of association of beriberi with malaria and diarrheal conditions, with gastrointestinal and heart disorders, anorexia, anemia, etc.; summary; bibliography; index.

The tables giving amounts of vitamin B present in different foods and vitamin to calorie ratios and the historical and critical discussions of various dietaries in all parts of the world will be of practical value to public health workers, clinicians, dieticians, as well as to investigators in nutrition.

The author has quoted and carefully analyzed many dietaries from European, Asiatic, African, and American countries, and has given special attention to dietaries in war prison camps, jails, asylums, etc., where "institutional diseases" are often found. From his analyses of these data it appears that no matter how poor the diets are in other respects, beriberi will not appear unless the vitamin to calorie ratio falls below a certain critical level. This apparent constancy of vitamin to energy metabolism is, in the reviewer's opinion, the most important generalization of the book. The quoted data on the influence of exercise, fever (as in malaria), hyperthyroidism, etc., on the development of beriberi leave no doubt of the existence of an intimate relation between energy and vitamin B metabolism.

The author's equations are too com-

plicated for review. Their central idea is that vitamin B needs of *mature* animals of different species (mice, rats, pigeons, dogs, and apparently humans) increase with the $2/3$ power of body weight, so that one equation can represent the vitamin B requirements of all mature animals including humans. This equation is further generalized to include growing animals by multiplying the $2/3$ power equation

$$(\text{vitamin} = K(\text{weight})^{2/3})$$

by the ratio of given body weight to maximum (mature?) body weight. In this connection it may be pointed out that the reviewer, using the method of least squares, obtains somewhat different values for the exponent of the weight for the species studied than Cowgill's 1.66, namely, 2.27 for mice, 1.75 for rats, 1.74 for pigeons and 1.69 for dogs. However, the author was probably justified in employing the 1.66 value for purposes of generalization.

This book makes an important contribution to technic by pointing out that anorexia is usually the earliest symptom of vitamin B deficiency, and by using this symptom for measuring vitamin B deficiency in diets. This fact has wide clinical application, especially in the feeding of marasmic infants and convalescents from fevers. Readers of this *Journal* will be grateful for the careful organization of the available knowledge relating to vitamin B and its deficiency diseases by an original and fruitful investigator.

SAMUEL BRODY

Children of Preschool Age—By Ethel Kavin. Chicago: University of Chicago Press, 1934. 340 pp. Price, \$3.50.

This report from the Behavior Research Fund and Institute for Juvenile Research in Chicago gives the results of studies in socio-economic status, social adjustment, and mental ability, with illustrative cases. The descriptions of

the nursery school and clinical services are clearly presented. The book should be helpful to anyone contemplating nursery school development, as well as a useful reference for those attempting to develop research at the preschool age level within a service program.

IRA V. HISCOCK

Community Hygiene—By *Laurence B. Chenoweth, A.B., M.D., and Whitelaw Reid Morrison, A.M., M.D.* New York: F. S. Crofts & Co., 1934. 317 pp. Price, \$2.50.

This book represents a crystallization of lectures to college students, and emphasizes especially measures for the control of communicable diseases. The excellent illustrations form one of the best features, many representing Ohio conditions, which add interest to the descriptive text. Selected references are appended to each chapter as a guide for more extended reading in various subjects. A brief glossary contains definitions "somewhat simpler than those given in the medical dictionary."

In general, the chapters are well written and include practical discussions of various aspects of preventive medicine and public health administration. One may wish that the definition of pasteurization were in accord with modern practice, and that a more representative picture of city health administration could have been given. But aside from a few details of this nature, the book has merit, and should prove to be a useful college text.

IRA V. HISCOCK

Microbiology and Elementary Pathology for the Use of Nurses—By *Charles G. Sinclair, M.D.* (2nd ed.) Philadelphia: Davis, 1934. 377 pp. Price, \$2.75.

In general the material presented is in good form, good diction, and well organized, but entirely too ambitious for the general garden-run of nurses.

This probably is not a legitimate criticism because there is always a question of what a nurse should be taught to make her a competent aid to the physician, and not his competitor. The more one sees of the training to which nurses are exposed the more he obtains the impression of inadequacy of that training.

While burdening the nurse with such things as the establishment of pébrine as a germ disease, too little emphasis is laid on the preparation of hands of operators and nurses and the site of the operation. The need, if not necessity, of running water for general cleansing is not mentioned.

There are a number of questionable terms and statements used, several improper statements and misleading impressions given, which markedly detract from the scientific value of the book; for example:

"Bacteria grow without the aid of chlorophyll"; "Ciliated epithelium which covers the bronchi"; "Thermal death point of bacteria of 65 to 70° C." (Time element and type of heat not mentioned); "Simple stains are merely weak *alcoholic* solutions of aniline *basic* dyes"; "Specimens." "Pus . . . may be . . . inoculated on to glass slides"; "The laboratory diagnosis of diphtheria includes bacteriological diagnosis . . . virulence tests, . . . and the Schick test"; "The war"; "Bacillus botulinus is found in fruits and vegetables"; "Overproduction of the parathyroid, (*hyperthyroidism*) will raise the serum calcium level"; "The beef tape worm has segments . . . 5 centimeters broad"; "Blood smears made by thinly *smearing* the drop of blood over a slide"; "Absence of insulin (as in diabetes)."

It is stated that the Widal test is of little value when the serum is from patients previously immunized against organisms of the typhoid group. This is far from true if the test is repeated at 3-5 day intervals, when by a stationary or changing curve the most valuable interpretation to be had by this method is shown. The agglutination titer progressively rises during the

activity of the typhoid or paratyphoid fever, irrespective of previous immunization. Diphtheria of wounds is not mentioned. Under the title, "Laboratory Diagnosis of Bacillary Dysentery," occurs the dangerous statement, "The laboratory may aid in the diagnosis of bacillary dysentery by a microscopic study of the cytology of the feces—the number and kinds of tissue, pus and blood cells there." In the discussion on immunity much is made of the use of the toxins in prophylactic immunization against scarlet fever. The wide usage credited to this procedure is questioned.

Under the causes of hypoglycemia, no mention is made of that occurring under excess of body prepared insulin as seen in some tumors of the islet cells of the pancreas. In the chapter on tumors occurs a statement that no student of oncology would accept: "There are forms of tumors *midway* between the sarcomas and the benign connective tissue tumors to which a combined name is given: fibrosarcomata, chondrosarcomata, osteosarcomata." The combined names represent that these are sarcomas and of the type cell as designated. There is no midway station—tumors are either benign or malignant, and the combined terms as used represent malignant tumors derived from elements whose names appear in the terms.

The printing and make-up of the book are good. M. PINSON NEAL

Textbook of Materia Medica and Therapeutics—By A. S. Blumgarten, M.D. (6th ed.) New York: Macmillan, 1934. 791 pp. Price, \$3.00.

Too bad this text was not used in teaching Materia Medica when we were student nurses. We would have been saved much confusion and despair. The author states that most texts on this subject are too technical, and we agree. Here is a physician who is a real teacher. He knows that a little

knowledge of normal physiology is necessary for an understanding of the drug presented. He knows that the effect of a drug is principally the thing a nurse should know about it, and the site of action is of secondary importance; what a drug does rather than where it does it.

He even begins with drugs that have simple actions which a nurse can easily understand, then goes on to those that stimulate gastric juice, then cathartics, then drugs which act upon the blood, etc., ending up with drugs acting on the nervous system.

In my opinion the text is far the best in its field on the market. The two nursing schools we have visited since receiving the book to review were using it as a text, and it is probably safe to say that it is more widely used than any other. It is to be recommended without reservations.

EVA F. MACDOUGALL

Text-Book of Meat Inspection—By Robert V. Ostertag. Chicago: Alex Eger, 1934. Price, \$10.00.

This is an entirely new book superseding and replacing the classic, *Ostertag's Handbook of Meat Inspection*. In his Preface, Professor Ostertag points to the success of his *Handbook*, which has gone through 9 editions in German and 4 in English, and explains his reasons for writing a new book instead of issuing a new edition of the old one. He felt that the textbook could be made more concise and give more attention to essentials, making it more useful to veterinarians. He holds that the value of the *Handbook* as a source of material remains unimpaired. The English editor, with the permission of the author, has reduced the size of the book by cutting out portions of the German edition, chiefly history, German legislation and German references. He has also added a chapter on poultry.

It is hard to speak too highly of this

work. Professor Ostertag has for many years been recognized as the greatest veterinary authority on meat inspection, and there are few people in any country capable of criticising his work. The book before us goes into the usual subjects found in a book on meat inspection, and gives an especially thorough description of the physiological conditions which are important. There is a chapter discussing the General Pathology of Slaughtered Animals Relating to Sanitary Science. Other chapters discuss Regional Diseases; Blood Anomalies; Intoxications and Auto-Intoxications; Animal Parasites; and Infective Diseases. A chapter is devoted to the use of agglutinants in sausage, the adulteration of meat, coloring and inflation.

There are a good index, and 12 appendices, a number of which are devoted to the laws and regulations in force in England. These concern slaughter, slaughter houses, food regulations, definitions of such terms as "cattle," "meat," "animal," etc.; General Observations for the Guidance of Inspectors and Butchers; Meat marking, Shops, Stores, Stalls, etc.; the use of preservatives, dyes, samples for analysis, and various other matters. Appendix XII is devoted to Regulations Governing the Meat Inspection of the United States Department of Agriculture. It will be seen that the book as issued in this country and England is especially designed to meet the uses of English and American veterinarians and food inspectors. The chapter on Animal

parasites occupies 80 pages, and that on Vegetable Parasites, really a treatise on infectious diseases, 203 pages.

The book is well printed and bound. The illustrations are abundant and good, many of them being in colors. The reproductions of the plates are excellent. This book can be recommended without reservation. While intended chiefly for the veterinary profession it is a standard reference for health officers and all engaged in the handling and inspection of foods. There can be no doubt that it will have a success comparable to the author's *Handbook of Meat Inspection*.

MAZÛCK P. RAVENEL.

The Mother's Encyclopedia—Compiled and Edited by the Editors of the Parents' Magazine. New York: Reynal & Hitchcock, 1934. 959 pp. Price, \$3.00.

On first thought one would hardly turn to an encyclopedia to learn how to bring up a child; but really in this instance the editors have done a pretty good job.

The subject matter consists of short articles by 130 authors (if my count is correct), many of them of national reputation. The unavoidable lack of continuity is balanced by the excellent system of cross references, a full subject index, and a table of contents grouped by age interest. The articles themselves are arranged alphabetically according to subject. Lesser but real advantages are good paper and type and flat opening. MERRILL E. CHAMPION

A SELECTED PUBLIC HEALTH BIBLIOGRAPHY WITH ANNOTATIONS

RAYMOND S. PATTERSON, PH.D.

Conserving Drinking Water—Inaugurating a series of abstracts of the report of the Water Planning Committee of the National Resources Board, this article presents an interesting picture of the meteorological conditions of the United States including a pictorial representation of the depths of mean annual precipitation.

BRUSH, W. W. Controlling Water Resources. *Water Works Engineering*, 88, 3:115 (Feb. 6), 1935.

Over a Century of Urban Tuberculosis History—An interesting and valuable review of tuberculosis mortality in American cities, and the social, economic and public health changes which probably influenced the course of that disease.

COLINSON, J. The Trend of Tuberculosis Mortality in Baltimore and Eight Other Cities, 1812-1932. *South. M. J.* 27, 12:992-1002 (Dec.), 1934.

Tuberculous Infection and Immunity—Epidemiologic evidence is presented which leads this Welsh author to conclude that relative immunity is acquired by mild tuberculous infection, though principally in those racial stocks long tuberculinized. It is pointed out editorially in the same issue that this conclusion is not in accord with the opinions of some American writers who now feel that tuberculin sensitization may well be regarded as a two-edged sword.

CUMMINS, S. L. Contact With Infection in Tuberculosis. *Canad. Pub. Health J.* 26, 1:1 (Jan.), 1935.

For Pension Planners—About 17 per cent of the population is over age 50; and 5.4 per cent over age 65. In 1920 only 4.7 per cent fell into this latter

class. The population is rapidly aging. Some of the New England States have nearly 9 per cent over age 65.

CUMULATIVE AGE GROUPS, BY STATES, FOR THE POPULATION 45 YEARS OLD AND OVER. Bureau of the Census. Washington (Dec. 28), 1934. (A distribution by color, age, and sex was issued Nov. 20, 1934.)

Fluorides and Teeth—From studies in West Texas, it now appears that cattle, too, may develop mottled tooth enamel when water rich in fluorides is used for drinking.

DEAN, H. T. Mottled Enamel in Cattle. *Pub. Health Rep.* 50, 7:206 (Feb. 15), 1935.

While Colds Go Merrily On—The conclusion that no specific measure has as yet been shown to be of sufficient value, for the prevention of colds to justify its indiscriminate use, though general measures carefully carried out seem effective in reducing colds among "cold susceptible" groups, follow logically, if not hopefully, upon this review of the present-day status of cold prevention and treatment.

DIEHL, H. S. The Common Cold. *New York State J. Med.* 35, 3:109 (Feb. 1), 1935.

In the Cause of Social Hygiene—Summarizing the reports of social hygiene activities of official agencies and voluntary groups in the 48 states in 1934, the picture presented is encouraging in certain respects. Though suffering from limitations of funds, a surprising number of agencies are doing business as usual.

EDWARDS, M. S., and PINNEY, J. B. Notes on the American Social Hygiene Scene 1934. *J. Social Hyg.* 21, 2:49 (Feb.), 1935.

For Improving on Ward Statistics—A highly practical manual on ar-

ranging for permanent statistical areas within cities, to insure continuity of data in spite of ward changes. Very timely in the light of the possible federal census in 1935.

GREEN, H. W., and TRUESDELL, L. E. Census Tracts in American Cities. Bureau of the Census. Washington (Dec.), 1934.

In One of the Wealthy Counties—Under the aegis of the County Medical Society and the Parent-Teacher Association, a scheme to examine children aged 2 to 5 was undertaken in Westchester County (N. Y.). Almost all of the 1,000 children examined needed medical attention. Only a few had been immunized against diphtheria or tuberculin tested; nearly a quarter had knock-knees and weak feet; and many behavior abnormalities were found.

HALL, F. Westchester County Child Health Examination Program. New York State J. Med. 35, 4:172 (Feb. 15), 1935.

The Price of Future Progress—How the status of public health administration may be restored at least to the position it held before the depression is the topic of this discussion addressed directly to voluntary health organizations, but with implications for all leaders in public hygiene.

HISCOCK, I. V. Rehabilitation of Health Work in the United States. Yale J. Biology & Med. 6, 6:1 (July), 1934.

Protection against Poliomyelitis—Twenty-five children were vaccinated with a ricinoleated poliomyelitis vaccine. None showed any ill effects and all showed an increase in antibody in the blood after vaccination. The authors feel they have a suitable vaccine for use particularly during epidemics.

KOLMER, J. A. *et al.* A Successful Method for Vaccination Against Acute Anterior Poliomyelitis. J.A.M.A. 104, 6:456 (Feb. 9), 1935.

Biting Flies from Sewage Filters—In the trickling filter bed of a South

Carolina Sewage treatment plant, stable flies were found breeding in great numbers. Flooding the filters twice a week for 12 hours solved the nuisance problem without damaging the nitrifying bacteria.

NETTLES, W. C. Checking an Outbreak of Stable Flies at Sewage Plant. Munic. San. 6, 2:36 (Feb.), 1935.

The Significance of the Colon-aerogenes Group—In stored feces, typical *B. coli* tended to disappear and were replaced by intermediate types, and then by typical aerogenes group. However, in some specimens, typical *B. coli* remained for a long period. The assumption that organisms of the aerogenes type, isolated from water supplies, come from grains or soils, and not from feces, is untenable.

PARR, L. W. Sanitary Significance of the Succession of Colon-aerogenes Organisms in Feces. Proc. Soc. Exper. Biol. & Med. 32, 4:580 (Jan.), 1935.

Amebic Dysentery and Food Handlers—Research is described which indicates that carriers of amebic dysentery do not frequently contaminate their hands with viable organisms under ordinary conditions. From this it is concluded that contamination of food by food handlers must occur infrequently.

SPECTOR, B. K., *et al.* Endamoeba Histolytica in Washings from the Hands and Finger Nails of Infected Persons. Pub. Health Rep. 50, 6:163 (Feb. 8), 1935.

What Staphylococci Are Implicated in Food Poisoning?—The question whether staphylococci causing food poisoning constitute a peculiar group must be answered in the negative, so long as our present differential methods remain with existing limitations, is the finding of this research.

STRITAR, J., and JORDAN, E. O. Is a Special Variety of Staphylococcus Concerned in Food Poisoning? J. Infect. Dis. 56, 1:1 (Jan.-Feb.), 1935.

Our Maternal Mortality is Excessive—About 1,000 certificates involving maternal deaths were sent to 16 foreign countries for classification. The differences in method of classification were found insufficient to account for the relatively high maternal mortality rate in the United States.

TANDY, E. C. Comparability of Maternal Mortality Rates in the United States and Certain Foreign Countries. Children's Bureau. Washington. Bureau Pub. No. 229, 1935. 5 cents.

Results of Sanatorium Care—The follow-up of 2,000 patients discharged from tuberculosis sanatoria finds half

returned to work and leads to the conclusion that results of sanatorium care are encouraging.

WHERRETT, G. J. Follow-Up Information on 2,031 Tuberculosis Patients One to Thirteen Years After Discharge from Sanatoria. Am. Rev. Tuberc. 31, 1:62 (Jan.), 1935.

Vitamin D Milk—Some rachitic infants were fed irradiated milk, others milk from yeast-fed cows. There was no indication of any difference between the two milks in their antirachitic effectiveness.

WYMAN, E. T., *et al.* A Comparison of "Yeast Milk" and Irradiated Milk in the Treatment of Infantile Rickets. New Eng. J. Med. 212, 6:257 (Feb. 7), 1935.

Skyline of Milwaukee

MILWAUKEE—OUR 1935 CONVENTION CITY

ON to Milwaukee and the Sixty-fourth Annual Meeting, October 7 to 10, 1935.

Magnetic Milwaukee, nestled in a broad expanse of bay, a part of Lake Michigan, one of the chain of lakes which holds half of the fresh water of the world, possesses a charm that has made it a successful convention city.

Milwaukee's recognition as a famous gathering place and as a center of genuine hospitality can be traced back through generations of red-skinned braves. Indian legend tells us that the name Milwaukee was first uttered as a naïve guttural cry of an Indian warrior as "Mahn-a-waukie" as he drew his bark canoe from the waters at the present site of the city. This name in the Ojibwa language means "good and beautiful lands." In different dialects other Indians are known to have called this spot "Mahn-a-waukie Seepe" or translated "gathering place by the rivers."

Shortly after the first Indian came to Milwaukee more and more tribes followed. They answered a beckoning message on the shores of Lake Michigan—a signal fire with a lone column of smoke, a bronzed figure standing nearby waving a blanket—this, the recognized Indian symbol for hospitality

and friendliness served to draw the warriors to a natural meeting place.

Soon this early Milwaukee was a village of tepees; a village inhabited by warriors who had buried their warring hatchets, washed the war paint from their faces and lived in peace and contentment where the three rivers—the Milwaukee, Menominee, the Kinnickinnic—brought the beaver, muskrat, the mink, and the otter to the waiting traps of Milwaukee's first residents.

Today, Milwaukee is the metropolis of Wisconsin, the twelfth most populous city in the United States. In the last decade its population has increased 121,000 and Milwaukee County, in its 141 square miles, has a population of 725,263.

The same spirit of friendliness and hospitality is common today among Milwaukeeans. Today there are no signal fires, nor bronzed figures, but in place of these there are thousands of smoke stacks of industry and many buildings towering into the sky with flags unfurled—symbolizing a great city with a great spirit.

Some two hundred years ago, Pere Marquette and Louis Joliet, on the way to the discovery of the Mississippi River, passed along the west coast of Lake Michigan and marked the site of

The Milwaukee Auditorium is located in the center of the hotel, theatre, and shopping district and is one of the most complete and serviceable buildings of its kind in America.

Milwaukee on their map. This map bearing the name of Milwaukee Bay is now in the possession of a convent in Montreal.

With the coming of the white man the Indian village grew into a thriving trading post, its strategic location giving it importance in the primitive commerce. In 1795 Jacques Vieau established a trading post for the Northwestern Fur Company.

Milwaukee traces its development as a city to the time when Solomon Juneau

purchased a small trading post from his father-in-law, Vieau, in an Indian village in the year 1818. Other pioneers banded together under the leadership of Juneau and were quick to capitalize on the advantages of the village's location for the development of industry and commerce.

The pioneers of Milwaukee, like their contemporaries in other sections of America, were generally able to handle their work unaided. But they joined together in the general spirit of coöpera-

The Lincoln Memorial Drive which stretches from downtown Milwaukee along the lake to the fashionable east side residential section follows Lake Michigan's edge through many parks and beaches. This view shows Water Tower Park and the Bradford Beach Pumping Station.

tion and worked for the combined interests and welfare of their neighbors, and thus the village prospered.

Along in the middle 30's Milwaukee suffered from an era of speculation, due to the high enthusiasm about all manner of public improvements. Roads were ordered and charters were granted to railroads. This was a little rash and prices mounted and real estate suffered. However, such men as Solomon Juneau made good on the pledges they had made and prices were soon restored to fair value.

Rival settlements known as Milwaukee East Side and Milwaukee West Side, popularly called Juneau Town and Kilbourn Town, were separately incorporated as townships of Milwaukee County in 1837. Two years later they were united as wards of the same village, each one keeping complete administration records of its own. Walker's Point on the south side of the city, was annexed as a third ward, and in 1846, the three were incorporated as the city of Milwaukee, and Solomon Juneau was elected the first mayor.

The first newspaper, the *Milwaukee Advertiser*, began publication on July 14, 1836, and a public school was also opened in that year.

In 1839, the Fire and Marine Insurance Bank was established. This bank for 40 years was one of the strongest banking houses west of the Alleghanies. Its notes passed at par through the panics when even government issues depreciated. It financed the Milwaukee Railroad and other railways.

The first connection with Chicago by Telegraph was established in 1849; by railway in 1856. About 1840 a stream of immigration from Germany began, which was accelerated by the revolutionary movement in 1848, and continued through half a century.

In 1900 out of a total population of 285,315, the number born in Germany was 53,854; 151,045 more had one or

both parents of German birth. This made a total of 75 per cent who were either German by birth or of the first generation.

Its traditions are rich—its people are hospitable, yet it enjoys even greater advantages as a convention city. It is easy to get to Milwaukee for it is central to the northern part of the United States. Conventions held here impose surprisingly low travel burdens upon entire delegations, for it is said that more convention-going people live within a day's ride of Milwaukee than any other city in the United States, with possibly several exceptions.

Come to Milwaukee by an overnight train ride or less; by motorcar over a network of fine hard-surfaced highways; by steamship over Lake Michigan which affords automobile transportation and overnight service; by airplane over Lake Michigan, or overland and arrive at a modern municipal airport only 3 miles from downtown Milwaukee.

Convention Headquarters: Schroeder Hotel

Matthew Keenan Health Center, Milwaukee, Wis.

You will enjoy Milwaukee! We view it as a bustling workshop—one of America's greatest production centers. With this scene of great activity and industrial progress, Milwaukee has maintained its pleasing picturesqueness which through years has endeared it to visitor and dweller alike.

Nature has provided a beautiful setting, and Milwaukee citizens, while building up large and diversified industries have not been insensible to the appeal of beauty.

The Milwaukee River flowing through the heart of the business district gives to the city a graceful charm. Its waters teem with commercial crafts; its banks are lined with industrial plants; picturesque bridges span this stream and atone in whatever measure necessary for the ravages of commerce.

Delegates and visitors to this Sixty-fourth Annual Meeting will enjoy the farsightedness of Milwaukeeans who planned Milwaukee's business area. You will like especially the way in which the hotels, theaters, restaurants, stores, and Auditorium are all situated conveniently to each other.

Milwaukee has many parks and playgrounds scattered throughout the city covering an area of more than 1,500 acres. These parks offer a variety of interesting scenery and recreation. The

city is also circled by a park development plan which follows the lake shore, and the courses of the rivers and a wide concrete driveway extends along 5 miles of the lake shore from Juneau Park in downtown Milwaukee to Lake Park near the north limits.

It is a city of homes and home-loving, pleasant folk. Beautiful residential districts in all parts of the city bear evidence to this fact.

Milwaukee, with its natural advantages for commerce, has arisen rapidly as an industrial center. Today it ranks first in more than 20 important lines of manufacturing in the United States. It is one of the largest steel casting centers and has turned out some of the largest steel and gray iron castings made in the United States; has some of the largest machinery construction shops in the world; has turned out large Diesel engines, the largest gas engines; has the largest and best equipped plant for the manufacture of electric traveling cranes and hoists in the United States.

Added to this we find large plants for the manufacture of mine hoists, cars, gears and controls, refrigeration machinery, enameling, boat motors, lumber, motorcycles, leather and shoes, food products and beer.

There is nothing more pleasing to Milwaukee visitors than the beautiful

Lincoln Memorial Drive which follows the shore line of Lake Michigan for a course of 6 miles through a series of parks and beaches, the Milwaukee Yacht Club, the Coast-guard Station, Milwaukee Gun Club and terminating in the wooded and ravined Lake Park.

The Milwaukee Yacht Club, nestling in a cove of the harbor, adds a picturesque to the lake front with its sailing vessels, motor boats and races and water sports.

Washington Park, on the far west side of the city, contains the zoo, one of the country's largest, and the only one which has successfully bred and raised polar bears. Mitchell Park on the south side is famous for its gorgeous conservatory and exquisite sunken gardens.

Another show place in Milwaukee is its fine museum and public library, housed under one roof in a handsome building near the Court of Honor. The museum is noted particularly for its early American characterizations, and its collection of Indian articles. The Layton Art Gallery and the Milwaukee Art Institute located at North Jefferson and East Mason Streets have very fine permanent collections.

As an educational center Milwaukee is proud of its schools and colleges. Marquette University welcomes students from all over the world. In addition to its graduate school and high school, special courses in liberal arts, journalism, business administration, law, den-

tistry, engineering, medicine, and music may be followed.

The Vocational School is one of the foremost of its type in the world. It enrolls 35,000 persons and has a faculty of 269. There are 70 different courses for boys and men and 35 for girls.

Then there is Milwaukee Downer College, an accredited women's college, offering degrees of B.A., B.Sc., and special courses for women, as well as the Extension Department of the University of Wisconsin providing instruction for 3,500 students.

Occupying an entire block in the downtown area is the new 10 million dollar Court House as an example of modernity. It is one of the buildings of a proposed civic center.

Make your plans now to be present at the Milwaukee convention—October 7 to 10. You will enjoy the inspiration that always comes from an annual reunion, and the splendid impulses that arise from attending sessions. The Local Committee is busying itself planning a meeting which will be a worthy addition to your store of memories.

And, today, this great metropolis invites you as did the friendly braves of the Ouisconsin village of long ago to sit by her council fires and smoke the pipe of peace—to enjoy the hospitality of this friendly city. You cannot fail to enjoy this land of beautiful scenery and pleasant climate that also is so rich in legendary and historic interest.

The Royal Institute of Hygiene

THE Executive Secretary of the American Public Health Association has been authorized to appoint a member or Fellow of the Association as a representative at the Royal Institute of Hygiene in England, June 4 to

9. Dr. Atwater will appreciate it if anyone who expects to be in England at this time will get in touch with him at the Association office, 50 West 50th Street, New York, N. Y.

ASSOCIATION NEWS

ORGANIZATIONS MEETING WITH THE A.P.H.A. IN MILWAUKEE

The following organizations will meet simultaneously with the American Public Health Association in Milwaukee, October 7-10.

American Association of School Physicians
International Association of Dairy and Milk Inspectors
Conference of State Sanitary Engineers
International Society of Medical Officers of Health
Association of Dairy, Food and Drug Officials
Conference of Wisconsin Health Officers
Conference of State Laboratory Directors
Association of Women in Public Health

The preliminary program plans include special sessions on The Rôle of a

Health Department in a Program of Social Security, Mental Hygiene, Professional Education, Veterinary Public Health, Diphtheria Immunization, and a session upon the history and achievements of the Association's Committee on Administrative Practice, celebrating its 15th anniversary.

The Fourth Health Education Institute will be held October 4, 5, and 6, prior to the opening of the several conventions. The subject will be "Health Education in Small Cities and Rural Communities."

VITAL STATISTICS COUNCIL MEETS

A MEETING of the Council of the Vital Statistics Section was held February 3, in New York, with the following members present: G. E. Harmon, M.D., *Chairman*, Jessamine Whitney, George H. Van Buren, T. F. Murphy, M.D., John O. Spain, John Collinson, M.D., and A. W. Hedrich, Sc.D., *Secretary*. The following business was transacted:

The Committee on Confidential Inquiry on Causes of Death was continued. Dr. G. E. Harmon is to be chairman and Marjorie Bellows, who, with Dr. Matthias Nicoll has been conducting a survey on this subject in Westchester County, was appointed Secretary. For the next report of the committee, the following subjects have been suggested: (1) relative value of various methods of confidential inquiry; (2) change in death rates effected through confidential inquiry under titles other than the two discussed in the first report; (3) ways and means of extending confidential inquiry to other areas.

Discussion of the future of the Committee on Accident Statistics was deferred until the annual meeting.

A Committee on Standard Tables was authorized with Dr. John Collinson as chairman.

The Committee on Forms and Methods of Statistical Practice was authorized to take steps looking toward a joint committee with the Epidemiology Section for investigating the desirability and feasibility of differentiating, in certain reports, between varieties of the same disease; for example, major and minor smallpox.

It was voted to revise the "Rules for Statistical Practice" adopted in past years by the Section. Dr. T. F. Murphy was appointed committee chairman, with power to add.

It was voted to promote coördination between committees of the Section and those of the Association of State Registration Executives, by giving representation on Section committees to the chairmen or other suitable members of the Registrars' committees. As an ad-

ditional help in coördinating activities and promoting friendly relations it was voted to invite the president of the Registrars, Dr. Stewart Thompson, to become an Advisory Member of the Council of the Vital Statistics Section.

It was voted not to approve the resolution adopted by the Arizona Public Health Association calling for allocation of tuberculosis deaths to the place of origin of the disease, that objective, however desirable, being impracticable as routine procedure. It was felt that such allocation should be a matter of local study. Allocation to place of usual residence is, however, to be commended.

A resolution was adopted favoring a 1935 federal census (see editorial section). The Council also expressed its interest in the problem of promoting accuracy of intercensal estimates of populations for rural and the smaller intra-state areas, but no specific action was taken at this time.

It was voted to conduct a membership campaign, to have the following phases: (a) each member of the Council to bring in 5 new members; (b) section members, who travel extensively, to be requested to invite new memberships as occasion permits; (c) professional groups to be covered by members as follows: State registrars, Dr. Stewart Thompson; City registrars, Dr. G. E.

Harmon; Insurance workers, George H. Van Buren; Health associations, Jessamine Whitney; Universities and foundations, Dr. A. W. Hedrich.

George H. Van Buren was appointed chairman of the Committee on Membership.

It was agreed, subject to approval of the Central Office, to prepare and circulate a directory of persons engaged in the collection, publication, or analysis of vital statistics. The directory, it is hoped will prove useful for program and and committee appointments, as an incentive to membership, and as a source of information as to who is who in vital statistics.

An outline of Annual Meeting sessions was tentatively adopted. There is to be a session for (a) committee reports and Section business, (b) registration problems, (c) needs of the various types of consumers of vital statistics, and (d) general papers.

It was voted to invite the Association of State Registration Executives to organize the session on registration problems, and to invite their President to chair the meeting jointly with the Section Chairman.

Votes of thanks were extended to Dr. W. J. V. Deacon for suggestions offered for the program, and to Dr. Dublin for the use of a meeting room.

A. W. HEDRICH, Sc.D., *Secretary*

APPLICANTS FOR MEMBERSHIP

The following individuals have applied for membership in the Association. They have requested affiliation with the sections indicated.

Health Officers Section

Joseph T. Brennan, M.D., Court House, Independence, Mo., Jackson County Health Commissioner

W. M. Brien, M.D., 449 Main St., Orange, N. J., Health Officer

Wheeler Davis, M.D., Kennett, Mo., Dunklin County Health Officer

Alfred D. Gregg, M.D., Asheboro, N. C., County Health Officer

Charles A. Harris, M.D., City Hall, London,

Ont., Canada, Medical Officer of Health
Jerome M. Jekel, M.D., 1800 E. Capitol Drive, Milwaukee, Wis., Health Commissioner of Shorewood

Morton L. Levin, M.D., Dr.P.H., Court House, Grand Haven, Mich., Ottawa County Health Officer

Zack P. Mitchell, M.D., Henderson, N. C., County Health Officer

William J. Owings, M.D., Vernon, Ala., Lamar County Health Officer

Dr. H. H. Pansing, 2603 Salem Ave., Dayton, O., Montgomery County Health Commissioner

Arnold L. Peterson, 116 Temple St., Los Angeles, Calif., Executive Assistant to Health Officer

Andrew J. Signorelli, M.D., City Hall, Clayton, Mo., Health Commissioner

F. Michael Smith, M.D., Vicksburg, Miss., County Health Officer

Laboratory Section

Joseph W. E. Harrison, 214 S. 12 St., Philadelphia, Pa., Lecturer, Philadelphia College of Pharmacy and Science; Consulting Chemist

Nell Hirschberg, M.A., 2900 Ellis Ave., Chicago, Ill., Assistant in Bacteriology, Michael Reese Hospital

Vital Statistics Section

Paul B. Cornely, M.D., Dr.P.H., Howard University, Washington, D. C., Assistant Professor in Public Health

Richard J. Learson, B.A., 4th & Broadway, Cincinnati, O., Associate Actuary, Western & Southern Life Insurance Company

Chettikulam N. Nayagam, 615 N. Wolfe St., Baltimore, Md., Student, Biostatistics Dept., Johns Hopkins School of Hygiene

Samuel A. Stouffer, Ph.D., University of Wisconsin, Madison, Wis., Professor of Social Statistics

William R. Tracey, B.A., Dominion Bureau of Statistics, Ottawa, Ont., Canada, Acting Chief, Vital Statistics Branch

Food and Nutrition Section

Bion R. East, D.D.S., National Oil Products Co., Harrison, N. J., Technical Consultant

James M. Frayer, B.S., Vermont Agricultural Experiment Station, Burlington, Vt., Dairy Bacteriologist

Walter H. Grunze, 622 W. 141 St., New York, N. Y., Inspector of Foods, Dept. of Health

Child Hygiene Section

Frances Johnson, M.D., 425 E. Wisconsin Ave., Milwaukee, Wis., Child Welfare Physician, Health Department

Frances M. Johnson, M.D., 719 Marion National Bank Bldg., Marion, Ind., Physician, Public Schools

Benjamin Lieberman, M.D., 2635 W. North Ave., Milwaukee, Wis., Child Welfare Physician, Health Department

Public Health Education Section

Charles St. J. Butler, M.D., U. S. Naval Hospital, Brooklyn, N. Y., Commanding Officer

Q. Edward Gatlin, B.A., P. O. Box 770, Jackson, Miss., Secretary, Committee on Post-graduate Medical Education, Mississippi State Medical Assn.

Public Health Nursing Section

Helen S. Ebbert, 505 Fulton St., Bay City, Mich., Public Health Nurse

Kathryn W. McCabe, R.N., 1219 N. 6 St., Boise, Idaho, State Supervising Nurse, E.R.A. Nursing Project

Ida M. Rainwater, U. S. Trachoma Hospital, Rolla, Mo., State Field Nurse

Opal Smith, R.N., St. John's Hospital, Jackson, Wyo.

Epidemiology Section

Esmond R. Long, M.D., Ph.D., Henry Phipps Institute, 7th & Lombard Sts., Philadelphia, Pa., Director of Laboratory

Unaffiliated

Marguerite M. Roe, R.N., 1732 Sheridan Ave., Whiting, Ind., County Medical Investigator

William M. Wade, P. O. Box 186, Westfield, Mass., Engineer, Westfield State Sanatorium

DECEASED MEMBERS

A. Brioso Vasconcelos, M.D., Mexico, Mex., Elected Member 1921, Fellow 1923

Lemar W. Andrews, M.D., Warsaw, N. Y., Elected Member 1919

M. Frances Etchberger, Baltimore, Md., Elected Member 1931

Harry F. Ferguson, Springfield, Ill., Elected Member 1916

John C. Humphreys, M.D., Philadelphia, Pa., Elected Member 1926

John Le Feber, Milwaukee, Wis., Elected Member 1913

Anna M. Scholfield, Providence, R. I., Elected Member 1932

Charles Strauss, New York, N. Y., Elected Member 1914

William H. Wakelee, Southbury, Conn., Elected Member 1933

DR. KENDALL EMERSON AND DR. JESUS E. MONJARAS ELECTED TO HONORARY FELLOWSHIP IN THE ASSOCIATION

ACTING on the recommendation of the Executive Board, the Govern-

ing Council has unanimously elected to Honorary Fellowship Dr. Kendall Emerson, past Executive Secretary of the Association, and Dr. Jesus E. Monjaras of Mexico City.

NEWS FROM THE FIELD

MENTAL DEFICIENCY

THE Annual Meeting of the American Association on Mental Deficiency will be held at the Hotel Palmer, Chicago, on April 25, 26, and 27. The sessions on the 25th and 26th will be devoted to studies on Mongolism; Birth Injury as an Etiological Factor in Mental Deficiency; Mental Disorders in Mental Deficiency; The Problem of Sterilization; Defective Delinquency and Its Relation to Penal Institutions; Community Supervision of the Paroled Mental Defective; and Newer Methods in Institutional Training for Community Life. The session on April 27, will be devoted to the sociological, psychological, and the special education aspects of Mental Deficiency. Complete data on the program may be obtained from the Secretary, Dr. Groves B. Smith, Godfrey, Ill.

INDIAN MEDICAL SERVICE

ONE feature of the new policy of the Indian Medical Service is to conduct Institutes as refresher courses for physicians and nurses. The first undertaking in this direction is scheduled for the Navajo Area physicians and nurses March 4 to 15. Two groups of physicians and two groups of nurses will sit at the feet of Dr. Walter Clarke of the American Social Hygiene Association in an Institute on Syphilis. This arrangement will afford all of our 20 physicians and most of our 62 nurses an opportunity to refresh themselves on the best accepted scientific practices relating to the diagnoses, treatment, and control of syphilis. With tuberculosis and trachoma, syphilis completes our triumvirate of scourges draining Indian health.

Another bit of news is the formation of an Indian Medical Society in the States of Arizona and New Mexico. The nucleus around which this organization was built was our Navajo physicians, but since there are Reservations in other parts of these two states, our Washington Office has proposed the formation of two additional branches; one for Arizona and one for New Mexico. It so happens that the membership will be 18 or 19 for each group.

These past months have been particularly hard ones for the Indian people in the Navajo Reservation because of the unusual incidence of influenza, measles, chicken pox, mumps, and pneumonia following measles or influenza. Our physicians and nurses have also been handicapped by an unusual precipitation in the form of snow and rain, making the roads almost impassable.—Excerpt from letter from W. W. Peter, M.D., Dr.P.H., F.A.P.H.A., Medical Director Navajo Area, Albuquerque, N. M., Feb. 26, 1935.

MASSACHUSETTS ASSOCIATION OF BOARDS OF HEALTH

AT the Annual Meeting of the Massachusetts Association of Boards of Health, held in Boston on January 31, 1935, the following officers were elected: *President*, Paul R. Withington, M.D., Milton; *First Vice-President*, Ernest M. Morris, M.D., Fall River; *Second Vice-President*, Curtis M. Hilliard, Wellesley; *Secretary-Treasurer*, G. Donald Buckner, Needham. Dr. Charles F. Wilinsky was appointed to represent the association on the Governing Council of the A.P.H.A.

The first two sections to be estab-

lished in the association are the Board of Health and the Laboratory Sections. These held their first meeting preceding the Annual Meeting, and elected the following officers for 1935: Board of Health Section—*Chairman*, Francis G. Curtis, M.D., Newton; *Secretary*, William O. Hewitt, M.D., Attleboro; Representative to Executive Committee, John J. McGrath, Salem; Laboratory Section — *Chairman*, Frank E. Mott, B.S., LL.B., Boston; *Secretary*, Roy F. Feemster, M.D., Boston; representative to the Executive Committee, Herbert E. Bowman, North Acton.

HADASSAH LAUNCHES RESEARCH PROGRAM

IN addition to curative and preventive work Hadassah will soon enter the realm of medical research and teaching. Through the proposed Rothschild-Hadassah-University Hospital in Jerusalem, which will be build by Hadassah and the American Jewish Physicians' Committee, large-scale research will be carried on in a number of diseases, including cancer. The new medical center will include a graduate school of medicine to be affiliated with the Hebrew University. The heads of the hospital research and teaching departments will include eminent scientists exiled from Germany.

SOUTHERN CALIFORNIA PUBLIC HEALTH ASSOCIATION

AT the Annual Meeting of the Southern California Public Health Association, held at Santa Barbara, Calif., on January 26, 1935, the following officers were elected:

President—Dr. E. B. Godfrey, San Bernardino

President-Elect—Dr. R. V. Stone, Los Angeles

First Vice-President—Dr. R. C. Main, Santa Barbara

Second Vice-President—Dr. W. F. Foxe

Secretary-Treasurer—T. P. B. Jones, Riverside

VENEREAL DISEASE ESSAY CONTEST

THE council of the British Medical Society for the Study of Venereal Diseases announces a prize of £18 to be awarded the best critical review dealing with any venereal disease considered from any angle. The essay selected for the prize will become the property of the council, and the council will be at liberty to publish in the *British Journal of Venereal Diseases* any paper other than the one receiving the award.

Contributions should be about 6,000 words, typed, and sent to the Secretary of the Society, 43 Queen Anne Street, London, W.1, before July 31, 1935.

ALABAMA COUNTY HEALTH DEPARTMENT DISCONTINUED

THE Geneva County Health Department has been discontinued in accordance with a decision of the Alabama Board of Commissioners. Dr. Lucius S. Nichols was the County Health Officer.

HEALTH UNIT OF THREE COUNTIES

A THREE-COUNTY health unit, which includes El Paso, Hudspeth, and Culbertson Counties, has been established under the supervision of Dr. Thomas J. McCamant, member A.P.H.A., Director of the City-County Health Unit of El Paso.

SUMMER ROUND-UP BEGINS

THE 11th annual Summer Round-Up of the Children, major child health project of the National Congress of Parents and Teachers, will soon be in full swing. Although May 1, National Child Health Day, is the official opening date of the nationwide campaign, parent-teacher associations already are busy with the preliminary work of securing the names of preschool children and preparing for the campaign. The object of the Summer Round-Up is to send to the entering grade of school a class of children as free as possible from remediable physical defects.

PERSONALS

KENDALL EMERSON, M.D., F.A.P.H.A., Director of the National Tuberculosis Association, spoke at the Second National Conference on Slum Clearance and Rehousing, in Washington, January 18, on the public health aspects of a national rehousing program. He stated that the spread of tuberculosis had been checked by public education, but the death rates in slum areas still equal the high mortality of the nation as a whole a generation ago.

LEONARD GREENBURG, M.D., Fellow A.P.H.A., Acting Health Officer of New Haven, has been placed in full charge of the Department of Health of New Haven. He succeeds Dr. John L. Rice, who left New Haven to become Health Officer of New York City.

WILSON CARTER WILLIAMS, M.D., member A.P.H.A., has been appointed State Health Officer of Tennessee. He has been a member of the Department staff since 1926, and succeeds Eugene L. Bishop, M.D., Life Member and President of the A.P.H.A., who resigned to become full time Health Officer of the Tennessee Valley Authority.

HENRY R. O'BRIEN, M.D., F.A.P.H.A., has been provisionally appointed Commissioner of Health in Cattaraugus County, N. Y., to fill the vacancy caused by the resignation of Reginald M. Atwater, M.D., who has become the Executive Secretary of the A.P.H.A. Dr. O'Brien was graduated from the University of Michigan and has spent some years in the Orient with the Rockefeller Foundation. He holds a Certificate in Public Health from Johns Hopkins, has been a County Commissioner of Health in Ohio, and for the last 6 months has been on the staff of the New York State Department of Health, Albany.

THOMAS J. LEBLANC, Sc.D., member A.P.H.A., has been advanced from Associate Professor of Preventive Medicine in charge of a new department of preventive medicine at the University of Cincinnati College of Medicine.

ROSSELL H. JOHNSON, M.S., formerly of the University of Pittsburgh, has been appointed social hygienist in the Palama Settlement, Honolulu, and part time professor in the University of Hawaii. He will give courses in social hygiene and eugenics.

JOSE FABELLA, M.D., member A.P.H.A., of Manila, has been appointed Commissioner of Health and Welfare of the Philippine Islands.

GEORGE C. RUHLAND, M.D., F.A.P.H.A., Commissioner of Health of the City of Syracuse, N. Y., since 1928, has accepted the office of Health Commissioner of the District of Columbia, to succeed William C. Fowler, M.D., member A.P.H.A., who has retired. Dr. Ruhland entered the field of public health in 1905. He became bacteriologist and then director of laboratories in Milwaukee Health Department, which position he held for 8 years. In 1914 he was appointed Commissioner of Health of Milwaukee, in which position he served until 1924, when he became Director of the Syracuse Health Demonstration on the staff of the City Department of Health. He was made Commissioner in 1928.

E. S. MACPHAIL, F.A.P.H.A., after more than 33 years' association with the statistical service of Canada, has retired as Chief of the Demography Division of the Dominion Bureau of Statistics. He entered the Canadian Civil Service in 1901 as Chief Clerk in the Fourth Census, became Superintendent of Compilation of the 1911 Census, and in that capacity introduced mechanical tabulation into the Census Office. In 1918 he took a

leading part in the organization of the registration system for births, marriages, and deaths in Canada. In the same year, the Dominion Bureau of Statistics was formed, and Mr. MacPhail was appointed Chief of the Demography Division, which embraced the census and, since 1920, the compiling of vital statistics. Mr. MacPhail has been a member of the Council of the Vital Statistics Section of the A.P.H.A. since 1930. Articles by him were published in the *Journal* on the subject of infant mortality in May, 1927; on accident classification in January, 1929; and on maternal mortality in June, 1932. He has also contributed extensively to Canadian journals. W. R. Tracey has, since Mr. MacPhail's retirement, been appointed Acting Chief of the Vital Statistics Office. A. W. H.

CHESTER S. BOWERS, B.S., member A.P.H.A., recently resigned as Director of the Health Laboratory of New Britain, Conn., to accept the position of Senior Microbiologist in the Bureau of Laboratories of the Connecticut State Department of Health, Hartford, Conn.

CHARLES M. PEARCE, M.D., member A.P.H.A., of McAlester, was appointed State Health Commissioner of Oklahoma on February 8.

PEARL L. KENDRICK, Sc.D., F.A.P.H.A., Bacteriologist of the Michigan Department of Health, recently received a grant for research in antigenic properties of bacillus pertussis from the National Research Council.

DR. MILTON R. KUKUK, of Toledo, O., has been appointed Health Commissioner of Lucas County, to succeed the late Dr. Fred F. Devore.

JAMES S. HOUGH, M.D., F.A.P.H.A., of Livingston, Ala., Health Officer of Sumter County, has been named District Medical Superintendent in charge of eleven counties.

DR. HENRY T. DONOVAN, of Marion,

Ala., has been appointed Health Officer of Shelby County, succeeding Dr. John M. Kimmey, of Columbiana.

DR. CECIL KENT DRINKER has been appointed Dean of the Harvard School of Public Health, effective September, 1935, to succeed Dean Dr. Edsall. He is at present Professor of Physiology and Acting Dean.

DEATHS

JOHN RUHRAH, M.D., prominent pediatrician, author and lecturer of Baltimore, Md., died March 10. He was president of the American Pediatric Society, 1925; of the Medical Library Association, 1927; of the Maryland Medical and Chirurgical Faculty, 1919; of the American Academy of Pediatrics, 1934; and of the Osler Historical Society since 1933. In addition to medical history, he specialized in nutrition, clinical pediatrics, poliomyelitis, and dietetics, and wrote many books.

DR. JABEZ NORTH JACKSON, City Health Director of Kansas City, Mo., since 1932, died March 18. In the Spanish-American War Dr. Jackson was chief of the Second Division Hospital, Second United States Army Corps, near Harrisburg, Pa. He was president of the American Medical Association in 1926.

DR. LUTHER C. PAYNE, Health Officer for 20 years of Liberty, N. Y., died March 16. He was Liberty's second health officer in 50 years.

DR. F. F. DEVORE, District Health Commissioner of Lucas County, Toledo, O., died recently.

CONFERENCES

March 31–April 7, National Negro Health Week—21st Annual Observance.

Number 5

Reaction of Familial Contacts to Scarlet Fever Infection*

J. E. GORDON, M.D., G. F. BADGER, GEORGE B. DARLING, DR. PH.,
AND SARAH S. SCHOOTEN, M.D.

*Division of Epidemiology, W. K. Kellogg Foundation, and the Herman Kiefer
Hospital, Department of Health, Detroit, Mich.*

VARIOUS epidemiological aspects of scarlet fever have been reported from observations of a relatively large group of patients isolated at the Herman Kiefer Hospital, Detroit. Studies limited to hospital patients fail to give a comprehensive idea of the epidemiological problems associated with this disease. Even in large cities the majority of persons with scarlet fever are not isolated at a hospital. Conditions affecting the transmission and control of the infection differ considerably when the patient remains at home. A great part of the information about the clinical nature of scarlet fever, and much of its epidemiological behavior have been determined by hospital studies, because of the greater ease with which precise and continued observations can be made, the facilities for laboratory examinations, the better opportunity for control of disturbing factors, and the generally

better available records. Information about a group of patients isolated at home, and studied as nearly as possible with equal thoroughness and with the same methods, offers the possibility of contribution to the broader problem.

Influenced by these considerations, an epidemiological survey of scarlet fever under home conditions was started in the summer of 1931 among an urban population of Detroit. The observations have extended through 3 years, and are concerned only with ordinary endemic scarlet fever, not with a sharp outbreak of the disease. The information from such a study cannot of course be given universal interpretation. In rural communities, for example, environmental conditions are different; there is variation in the multiplicity of contacts, in response to the infection, and assuredly in the opportunity for continued transmission of the infectious agent. Nevertheless, a more exact appreciation of the epidemiological problems in urban communities can in all likelihood be obtained through comparison of this information with the be-

* Read before the Epidemiology Section of the American Public Health Association at the Sixty-third Annual Meeting in Pasadena, Calif., September 5, 1934.

havior of the disease in a group of hospital patients, studied by essentially the same methods.

A variety of interests have naturally been involved in this field study of scarlet fever. Information was desired on the reservoirs of infection during the time when scarlet fever was at a low level in the community, and on the factors involved in school epidemics, their origin, development, and extent. General opinion has catalogued scarlet fever as a disease whose transmission is related more to carriers than to contact with actual cases. A quantitative evaluation was desired. An answer has been sought as to how scarlet fever is introduced into families; and an attempt made to determine the effectiveness of various administrative procedures for the control of the disease, particularly isolation. The material in this report is restricted to the reaction of the familial contacts in homes invaded by scarlet fever infection.

METHOD

The area selected for study represents one of the sanitary districts of Detroit. The population, 100,000, was sufficient to permit adequate data. The district is residential, and the population principally white. A very small negro population is included, but scarlet fever occurred in only 2 colored families in the course of these observations. About one-third to one-half of the population is in average economic circumstances, with living conditions representative of the usual residential area in Detroit. The area also has two relatively poor neighborhoods, one with a population principally of Italian origin, the other native born; and two better than average residential districts, one of which is a university neighborhood.

Field studies were started in the summer of 1931 and continued uninterruptedly until the summer of 1934. An epidemiological investigation was made

of 1,097 families in which cases of scarlet fever were reported. The primary cases of 732 families were isolated at home, and 365 at the hospital for communicable diseases.

This study was definitely independent of the work of the regular staff of the Health Department. They made their usual investigations and effected their usual recommendations without influence. No attempt was made to correct deficiencies in control that we might discover independently, such as an unrecognized and unreported infection. The greater benefit was thought to rest in determining the behavior of scarlet fever infection under usual and ordinary circumstances.

The first visit to the home was principally devoted to obtaining information about the source of the infection. Schoolmates, playmates, and all other persons involved were later investigated. Record was made of the age, past history of scarlet fever, and number of familial contacts. The Dick test for immunity to scarlet fever was made at this time, and cultures were prepared from swabbings of the nose and throat, to be examined for the presence of hemolytic streptococci.

A second visit was made the following day. The results of the Dick test were determined, and inquiry was made regarding other illness and possible extension of the infection among members of the family. Subsequently, visits were made at the end of the first and second weeks. The purpose was to determine if others of the family had contracted scarlet fever, or had been ill with any acute infection, and for the original patient to determine the course of the disease, and the presence or absence of complications.

The fifth visit was made at the end of 4 weeks, about the time that isolation was terminated, in order to determine the clinical condition of the patient, and particularly the factors which might

account for transmission of infection after release. Some of the patients had been isolated at the hospital and some at home. A comparison was made of the reaction of contacts after isolation by these two methods.

The next visit was about 8 weeks after the onset of the original infection. The behavior of the contacts in the intervening month was recorded and all of the events in the course of the preceding 2 months were reviewed and summarized. Contacts with an originally positive Dick reaction were retested. Some of those who had reacted negatively were also tested. Cultures were again taken for hemolytic streptococci. The final visit was made the next day to determine the result of the Dick test.

The first and sixth visits were by a physician, the others by one of two specially qualified nurses, carefully trained in epidemiological methods. Special visits to investigate a new case, indeterminate illnesses, or other unusual circumstances were made by the medical epidemiologist.

Every home with a case of scarlet fever was visited, but records are not complete for all. Most of the patients were under the care of private physicians. Before epidemiological investigation was undertaken the approval of the physician was asked, and almost always obtained, but there were exceptions. Because of this procedure, some delay in making the first visit to the home was unavoidable. This was sometimes possible on the same day that the case was reported, but the following day was more usual. Some contacts had by that time already been removed to the home of an adult friend outside of the isolation area. Many times the wage earner had taken other quarters. In rare instances the head of the family refused permission, but one of the encouraging features of the study was the ready cooperation encountered. Occasionally, because of the stress of in-

creased numbers of reported cases during the season of greatest prevalence, epidemiological investigation could not immediately be made. Later, as conditions permitted, this was done, but no investigation made later than 1 week after the first reported case is included in this report.

PAST HISTORY OF FAMILIES WITH SCARLET FEVER

In the course of the 3 year study, scarlet fever occurred in 1,097 families in the area studied, with at least 1 case in each. The number of individuals in these families was 5,352; 2,455 were children less than 15 years of age and 2,897 were adults. The previous occurrence of scarlet fever in this group is shown in Table I. Relatively few (9) of the 670 children less than 5 years of age had previously had scarlet fever. The proportion in the age group 5 to 9 years was distinctly greater, 84 (7 per cent) of 1,194. Of 591 older children, aged 10 to 14 years inclusive, 87 had had scarlet fever, or 14.7 per cent (Table I).

TABLE I
AGE DISTRIBUTION OF INDIVIDUALS IN FAMILIES WHERE SCARLET FEVER OCCURRED,
ACCORDING TO HISTORY OF PREVIOUS SCARLET FEVER

Age	No Previous Scarlet Fever	Previous Scarlet Fever	Uncertain about Previous Scarlet Fever	Totals
0- 4 yr.	654	9	7	670
5- 9 "	1,100	84	10	1,194
10-14 "	494	87	10	591
15 + "	1,923	688	286	2,897
Totals	4,171	868	313	5,352

The number of adult persons who gave a history of previous scarlet fever was 688 of 2,897 questioned, or 23.7

per cent. The proportion was so unexpectedly great, that a check was made by examining a sample of the records of scarlet fever patients reported in Detroit during the first 6 months of 1934. The frequency of previous scarlet fever among adult contacts was found to be 16.4 per cent. These data were obtained in the course of the usual public health investigation by many different public health nurses. This percentage is also measurably higher than one would have anticipated.

Before scarlet fever entered this group of 1,097 families, 180 of the 2,455 children and 688 of the 2,897 adults had already had scarlet fever.

SCARLET FEVER IN FAMILIES

Knowing the past history of scarlet fever in these family groups, the circumstances are now presented under which scarlet fever subsequently occurred. All of the family groups had at least 1 case of diagnosed and reported scarlet fever. Although the number of families was 1,097, 1,102 cases of scarlet fever are considered to have been primary infections. In 3 families the disease developed simultaneously in 2 persons, and in one instance 3 cases developed on the same day. This accounts for the discrepancy between the number of families and the number of primary cases.

Scarlet fever usually appeared suddenly in an otherwise healthy group (868 families). The source of the infection is not of present interest. In 30 instances, the first reported case was actually not the initial invasion of the household. Some other member of the family group had previously had an acute infection whose identity as scarlet fever was first recognized when the second case developed, the 2 being reported at the same time. The interval between the 2 was always more than 4 days, that being our interpretation of the limit of acceptable reporting. The

original infection in 41 other families was an undiagnosed case, determined by epidemiological investigation but never reported by the attending physician. Throughout the isolation period these patients were not restricted from association with contacts.

In this report the term undiagnosed scarlet fever will refer to unrestricted persons with a history of an acute illness compatible with that of scarlet fever, and will indicate actual observation by the epidemiologist of either a scarlatiniform eruption of the skin, or the typical desquamation of scarlet fever.

In a considerable proportion of families (158) an interesting and unsuspected observation was made. An indeterminate illness of the upper respiratory tract in another member of the family had shortly preceded the appearance of scarlet fever. The usual interval between such illnesses and the appearance of scarlet fever was about 1 week, sometimes 3 or 4 days, occasionally 2 weeks. Most of these infections were tonsillitis, although a not inconsiderable number resembled common colds. In subsequent tabulated data, distinction is made between the two. A number were strongly suggestive of scarlatinal infections, but our requirements for classifying an infection as undiagnosed scarlet fever were strict. Two examples of such questionable infections are in point.

Case 1—A woman, aged 34, had fever, sore throat, and headache. She noticed no eruption of the skin. Twelve days later a daughter, aged 4 years, developed scarlet fever. The previous illness of the mother was recorded at this time. Physical examination showed suggestive but indefinite desquamation, limited to the ends of the fingers. Her illness was classed as tonsillitis. The child had had no known exposure to scarlet fever.

Case 2—A boy, aged 5, had fever, vomited, did not complain of sore throat, had a discharging nose, and when seen 3 days later gave the impression of having a slight subcuticular flush, perhaps compatible with a

disappearing rash, but this was decidedly indefinite. The mother stated that she had noticed no rash. The tongue appeared normal. Cultures of the throat contained hemolytic streptococci. Desquamation was never observed. The illness was classed as an upper respiratory infection. The mother developed classical scarlet fever 3 days after the onset of the boy's illness.

Often such illnesses were not limited to a single member of the family; 206 individuals were involved in the 158 families in which this circumstance was noted. In 3 of the families the succession of events was a nonspecific illness, then an undiagnosed case of scarlet fever, and finally recognized scarlet fever (Table II).

TABLE II
ILLNESSES IN FAMILIES BEFORE
RECOGNITION OF SCARLET FEVER

	Number of Families	Number of Persons Ill
No illness	868	—
Scarlet fever, unrecognized until second case	30	41
Scarlet fever, undiagnosed	41	43
Upper respiratory disease	158	206
—with hemolytic streptococci	70	78
—without hemolytic streptococci	54	78
—not cultured	34	50

In connection with these illnesses which preceded scarlet fever there are two points of interest: (1) Were they streptococcus infections? (2) Are they to be considered the means by which scarlet fever was introduced into the family? The idea that scarlet fever may exist in larval form is of course not new, nor has the possibility been

neglected that this is one of the ways in which it is transmitted. Many reports are on record. Information is lacking in regard to the quantitative importance.

Cultures from the nose and throat of persons with antecedent illnesses were made at the time the first case of scarlet fever was reported. It will be recalled that this was shortly after the onset of the reported case. It was manifestly impossible to know their nature earlier, because it was the reporting of scarlet fever which initiated the investigation. Cultures were taken from 156 persons; hemolytic streptococci were present in about half. Streptococcus infection is suggested. It is possible also that these patients may have developed, a carrier condition through contact with the patient with scarlet fever, and that the original illness was not of streptococcal nature.

Whatever the interpretation, individuals with these illnesses preceding scarlet fever had the highest hemolytic streptococcus rate (50 per cent) of any group of contacts. Other members of the same families but without an upper respiratory infection had a rate of 23 per cent. Members of families free from infections of this kind had the lowest rate, 17 per cent (Table III).

Contributing pertinently to the interpretation of these illnesses is the fact that people with such antecedent upper respiratory infections did not develop scarlet fever with anywhere near the same frequency as did contacts in general (ratio 1:3), despite the fact that hemolytic streptococcus invasion of the upper respiratory tract was more frequent. Many unusual circumstances determined by epidemiological investigations contributed strongly to the belief that it was by this means that scarlet fever was introduced into families. Numerous interesting examples could be cited, but the following are typical:

TABLE III
HEMOLYTIC STREPTOCOCCUS CARRIERS
AMONG CONTACTS TO PATIENTS WITH SCARLET FEVER

Totals	141	32.8	289	67.2
Contacts to cases where no illness preceded the first case	332	16.8	1,649	83.2

Case 3—One of 2 boys contracted scarlet fever. They were class-mates, friends, and both were 7 years of age. Three days later the second boy had a severe sore throat, fever, and headache, but no eruption and no subsequent desquamation. After another interval of 3 days his brother, aged 9, developed typical scarlet fever. On the same day a 12 year old sister was also acutely ill, had an indefinite eruption, was not considered to have scarlet fever, but later desquamated. On the day following these 2 infections a 15 year old brother developed a sore throat, of much the same nature as the original infection of the 7 year old, without eruption and, as determined by later investigation, without desquamation.

Case 4—An intimate playmate of a boy, aged 8 years, developed an acute sore throat. Whether or not this was the source of the second infection is impossible to determine with exactness. At any rate, 10 days later the second child developed sore throat and after another 11 days, an abscess of a cervical lymph node was incised. The child had no rash at the time of the acute illness and never desquamated. Three days after the gland was incised there were 3 outspoken cases of scarlet fever in the family, affecting children aged 6, 8, and 12 years. The sudden appearance of these 3 cases on the same day indicates an infection from a single source. Two days later another child, aged 3 years, developed scarlet fever, apparently secondary to one of the other 3.

Case 5—Two visitors, a man and wife, were house guests at the home of friends. In the course of their journey, the lady had developed a sore throat, present at the time of their arrival. No rash was noted, nor was there subsequent desquamation. Three days later an adult member of the family developed a sore throat, said to have been of relatively severe nature, but unaccompanied by a rash. Four days later a child, aged 3 years, had typical scarlet fever. Later both the mother and the child desquamated typically. Hemolytic streptococci were demonstrated in cultures from the throats of both visitors, the mother and the child.

The likelihood that such throat infections are many times of scarlatinal nature has long been accepted. Examples like those given are not unique. A quantitative evaluation of such infections as a possible factor in the spread of scarlet fever has not been made. In this experience such nonspecific illnesses preceded scarlet fever in 14.4 per cent of families.

ORIGIN OF SECONDARY CASES

Family contacts exposed to an original case of scarlet fever included 4,250 individuals, of whom 1,446 were children and 2,804 were adults.

The number who thereafter developed recognized and reported scarlet fever was 266. All cases occurred at least 1 day after the original infection and within 2 months. In addition 44 other persons had unrecognized scarlet fever subsequent to the original reported illness in the family and likewise are secondary cases but were never reported. They are to be added to the 266, making in all 310.

How was scarlet fever spread from the original case to a healthy contact? About one-third are attributed to direct contact infection from the original case; that is to say, transmission was from case to case. This was true for 93 of the recognized secondary cases and 11

of those undiagnosed. This interpretation was made only when the interval between cases was less than 1 week. The usual time was 2, 3, or 4 days. This does not eliminate the possibility of carriers, but it is felt that case to case transmission is the most likely interpretation (Table IV).

Another group of secondary cases was considered to have developed through the agency of contact carriers. When this interpretation was made, the original patient had been isolated at least 1 week, and there had been no intermediate cases. A second type of carrier includes persons with intermediate illnesses of the type described as often preceding scarlet fever. Eighteen

Totals	179	87	266	35	9	44

secondary cases are thought to have originated from such persons. Three-fifths of those investigated were found to harbor hemolytic streptococci in the upper respiratory tract. The third group of carriers disseminated the infection after release from isolation; convalescent carriers. Transmission of infection was of this nature in 41 instances. Hemolytic streptococci were demonstrated in some member of about one-half of the families when the secondary case was supposed to have originated from a carrier.

Still another part of the secondary infections originated from cases of scarlet fever not discovered until a second person developed the disease. Thirty of these original cases were then reported as scarlet fever; 41 never were. Of the secondary cases they caused, 83 were reported and 9 were not. It is difficult to classify secondary cases of this origin as representing case to case transmission or infection by carriers. Arbitrarily, if the secondary case occurred within 1 week of the original illness it has been listed as due to contact with a case; and if the interval was longer, as arising from a convalescent carrier. Recognizing the inexactness which must enter into such an arbitrary division, 40 of this group of secondary cases have been attributed to the acute infection of scarlet fever, and 52 to the agency of carriers, either healthy or convalescent.

Distributing all secondary infections according to isolation of the primary case at home or in the hospital, 102 cases secondary to patients isolated at home are considered as due to infection from a case, and 112 to carriers. For hospital cases the distribution is somewhat different in that 43 were of carrier origin and 53 from cases.

Scarlet fever in general is considered a disease largely arising from intermediate carriers, providing unknown sources are included as carriers. There

is no reason to doubt this opinion from our experience but certainly in this problem of secondary cases among familial contacts, case to case transmission is an equally important consideration. This is true whether the patient was isolated at home or in the hospital.

REACTION OF CONTACTS TO THE INFECTION

Previous discussion has been concerned with the nature of the original infection in families where scarlet fever appeared and the means by which it gained entrance into the family. Attention is now directed to what happened thereafter, the reactions of the contacts to the infection. As indicated, a considerable number developed scarlet fever; others had scarlet fever as certainly as the first group, but the disease was not reported. They are classed as having undiagnosed scarlet fever.

A third group of people contracted sore throat which, so far as could be determined by questioning or by observation, was unattended by an eruption; and definitely, by observation, was without desquamation. A fourth group had upper respiratory infections of the general nature of common colds subsequent to the appearance of scarlet fever in the family, likewise without eruption or desquamation of the skin. The great majority of the contacts had no illness (Table V).

The number of persons who were reported as having contracted scarlet fever subsequent to an initial primary case, either diagnosed or undiagnosed, was 266, and the secondary attack rate is thus determined as 6.3 cases per 100 contacts. Seven of these persons had a history of previous scarlet fever and presumably the current illness represented a second attack. The correctness of the information about previous attacks of scarlet fever depends upon the statement of the individual. It was

not always possible to verify this, because of residence in another city at the time, failure to remember the date, or other factors. One of the 7 persons was a child, of 163 children previously stated to have had scarlet fever. Of 687 adults with a history of previous scarlet fever, 6 had attacks in the course of these observations. The attack rates are essentially the same for both children and adults with a previous history of the disease (respectively 0.6 and 0.9 per cent). For those who presumably had not had scarlet fever the attack rate was 13.3 per 100 children and for adults 2.4. The differences are significant and indicate the general reliability of histories. In this connection, it may be noted that for primary cases of this series, 18 gave a history of previous attack (1.6 per cent), almost twice the proportion observed for secondary cases—17 were children. Even with allowance for inaccuracy of histories, second attacks of scarlet fever are seemingly more frequent than commonly supposed.

The rate for undiagnosed scarlet fever

was for children 3.0 per cent and for adults 0.3. In the 2 instances with a history of previous attack the attending physician stated that if he had not seen the child previously with the same illness he would certainly have called the present illness scarlet fever.

Combining both diagnosed and undiagnosed scarlet fever infections, the secondary attack rate for children with previous history of the disease was 1.8 per cent and for adults 0.9 per cent. For those without knowledge of previous scarlet fever the rates were 16.3 for children and 2.6 for adults. The total secondary case rate was 7.3 per cent.

A not inconsiderable number of exposed contacts had upper respiratory infections subsequent to the appearance of scarlet fever in the family. There is no really significant difference between the number of such infections that developed among persons with a history of previous scarlet fever, and among those who had not had the disease. These infections were more commonly accompanied by hemolytic

streptococcus invasion than not; also the proportion of those with hemolytic streptococci in cultures from the nose and throat was greater in the group who had had scarlet fever. The number in the latter group who contracted scarlet fever was naturally smaller. With less rigid requirements for determination of undiagnosed scarlet fever, some of these infections on purely clinical grounds would have been so classified.

Information concerning immunity to scarlet fever as judged by the Dick test, is available for a considerable proportion of the contacts in this series. The

technic of making the tests was that commonly employed. Particular attention was directed to preparation of syringes and needles, in order to avoid emphasized sources of error. The material for the test was supplied by the State Department of Health Laboratories. The tests were read after 22 to 26 hours, with results of positive and questionable tests recorded by actual measurement of the involved area of skin. Data presented in Table VI are limited to tests performed shortly after the entrance of scarlet fever into the family, with the further provision that the contact had had no recent ante-

TABLE VI

ILLNESSES IN INDIVIDUALS EXPOSED TO SCARLET FEVER, ACCORDING TO REACTION TO DICK TEST AND HISTORY OF PREVIOUS SCARLET FEVER

cedent illness. Many additional tests were made, but excluded for these reasons. The Dick reaction is known for 1,289 persons who met these requirements. The group includes 561 children and 728 adults (Table VI).

Of persons with no history of having had scarlet fever, 79.7 per cent reacted positively to the Dick test for ages under 5 years; for ages 5 to 9, 79.3 per cent; for ages 10 to 14, 69.0 per cent; and for adults in excess of 15, 25.2 per cent. The attack rate for scarlet fever among persons with a known positive Dick reaction was for children 12.5 per cent and for adults 4.6 per cent. If to the group with recognized and reported scarlet fever infections there are added those who had undiagnosed scarlet fever, the attack rate for children with Dick positive reactions is 15.4 per cent and for adults, 5.3 per cent.

Twelve persons with an original negative Dick reaction contracted scarlet fever; 7 among 146 children, and 5 among 577 adults. The difference between the attack rate for persons with positive tests is pronounced. Most

observers who have reported on the frequency of scarlet fever among groups who have been Dick tested, have recorded some few cases among persons who reacted negatively. Considering the age distribution and the intimacy of exposure in family groups, the number of cases among negative reactors, although somewhat more than average experience, is not excessive.

When a person had a positive Dick test and hemolytic streptococci were demonstrated in cultures from the nose or throat at the time of the original investigation, the proportion who subsequently contracted nonspecific illnesses of the tonsillitis and upper respiratory type was 17.5 per cent. Those with positive Dick tests but no demonstrated hemolytic streptococci later had illnesses of this nature in 16.0 per cent (Table VII).

IMMUNITY REACTIONS

What is the end result in regard to immunity, the aftermath of scarlet fever infection in these families? A large group of persons, 1,412, for all practical purposes can be considered to have

TABLE VIII
INDIVIDUALS ORIGINALLY DICK POSITIVE
WHO WERE RETESTED 2 MONTHS AFTER EXPOSURE TO SCARLET FEVER

	Intermediate Illness								
	Diagnosed Scarlet Fever	Undiagnosed Scarlet Fever		Tonsillitis		Upper Respiratory Infection		None	
Hemolytic Streptococci:		+	-	+	-	+	-	+	-
Number observed	7	6	5	24	23	17	21	45	180
Number becoming negative	5	4	4	14	13	10	9	12	19
Per cent becoming negative	71.4	66.7	80.0	58.3	56.5	58.8	42.9	26.7	10.6

developed immunity to the disease through having had an attack of scarlet fever. Many others were immune before scarlet fever entered the home. Particular interest attaches to the supposedly susceptible persons who did not contract the disease. A goodly number of these initially had a positive Dick test. Not a few were found to react negatively to this test after 2 months, without having had recognized scarlet fever infection. Persons judged susceptible and subsequently contracting tonsillitis while scarlet fever was in the home, developed immunity in about 60 per cent of instances, as determined by the change from a positive to a negative Dick reaction. The number was essentially the same, whether or not hemolytic streptococci had been demonstrated at the time of the original exposure.

The proportion who became Dick negative is rather striking because, of a group of patients with known scarlet fever (18), tested under the same conditions, 72 per cent changed from a positive to a negative Dick reaction. This number is small, but the result is supported by observation of

another group of more than 200 patients with scarlet fever and an initially positive Dick test; those reacting negatively when tested shortly after the appearance of the eruption being excluded.

The number of Dick positive reactors who became negative after having had an upper respiratory infection was slightly less, 50 per cent. If streptococci were demonstrated when first exposed, or during the illness, the proportion which became Dick negative was almost as great as for persons with actual scarlet fever. When streptococci were not demonstrated the Dick test became negative in 43 per cent (Table VIII).

Especial interest attaches to those who had no illness whatsoever during the time that a patient with scarlet fever was in the home. Nevertheless, 14 per cent had a change from a positive to a negative Dick reaction. When hemolytic streptococci were demonstrated, 26.7 per cent became negative to the test; in the larger group where hemolytic streptococci were not demonstrated, 10.6 per cent. These observations are significant in support of the

theory of latent immunization, a belief largely based upon epidemiological behavior of disease and not actual proof of immunity relationships before and after exposure. This evidence contributes to a quantitative evaluation of the phenomenon; the effect that can be expected from a relatively intimate exposure.

Information is not at hand concerning the permanency of this change from a positive to a negative reaction. Some few found to be negative 2 months after the original exposure are known to have become positive again, by retests made 2 years later. In Table VI it was shown that persons who gave a history of previous scarlet fever did not always have negative Dick tests; 32 of 211 were positive. It is known that not all patients convalescent from scarlet fever have developed a negative Dick reaction when tested at the end of 30 days. Various observers have noted persistent positive Dick reactions under such conditions varying from 5 to 40 per cent. It is quite possible that a Dick test, which has been negative shortly after scarlet fever, may again become positive as immunity varies from time to time. That is known to happen after active immunization by scarlet fever toxin. The same phenomenon may be concerned in these infections, and the test of whether or not permanent immunity actually developed will be found in the further history of these children in regard to scarlet fever.

SUMMARY

An urban population of 5,352 individuals, comprising 1,097 families invaded by endemic scarlet fever, had a secondary attack rate of 7.3 per cent. This includes diagnosed and undiagnosed cases.

Presumptive evidence is presented to indicate that many times scarlet fever first appears in the home as a simple upper respiratory infection, presumably

in an immune or partially immune person, from whom the infection is transmitted in the form of classical scarlet fever to a non-immune individual.

Failure to recognize scarlet fever when first it appears in families contributes distinctly to an increased secondary case rate. The function of the undiagnosed case in transmission of the infection is important; 31.6 per cent of secondary cases were due to that cause.

There is excellent support for the belief that in general scarlet fever is a disease largely transmitted by carriers rather than by cases. This, however, is not true of familial scarlet fever, because as many secondary cases were found to arise from exposure to the acute infection as from contact with healthy or convalescent carriers.

Upper respiratory infections including tonsillitis are relatively prevalent among persons recently exposed to scarlet fever.

Evidence is introduced that many of these infections are associated with a developing immunity to scarlet fever, judged by the Dick reaction. This occurred in the present experience to an extent comparable to that with clinical scarlet fever.

Latent or sub-clinical infection was the probable explanation of the immunity which developed in 14.8 per cent of contacts to patients with scarlet fever. This occurred more commonly when hemolytic streptococci were demonstrated in cultures from the nose and throat. Indication is given of its relative importance in establishing the progressive increase in immunity known to occur with advancing age and without disease.

An attempt has been made to evaluate quantitatively the relative importance of case to case infection, missed cases, larval infections, and carriers in the transmission of scarlet fever.

From the standpoint of public health

administration, 3 things can be emphasized. Need exists for earlier recognition and isolation of cases. Too many secondary infections arise from this deficiency. When secondary cases occur in families, the interval is usually short. This substantiates the recent

emphasis on a shorter period of isolation as being equally effective. In sharp outbreaks of scarlet fever, measures should be developed for the brief restriction of persons, particularly familial contacts, who have sore throat or other infections of the upper respiratory tract.

Soviet Plans Medical Zoo

A MAMMOTH zoölogical garden whose inhabitants will annually be sacrificed to the cause of science at the rate of 9,000 dogs, 7,000 cats, 21,000 rabbits, and 16,000 porpoises will be only one feature of the new medical center which the Soviet plans to start building on the outskirts of Moscow this coming spring, according to a dispatch from Moscow to *New York Sun*.

According to plans this will be the medical center of medical centers, and will automatically bring the Soviet Union to the front in the field of experimental medicine. The entire layout will cover about 1,000 acres, comprising separate but coördinated institutes devoted to research in morphology, physiology, psychology, biophysics, biochemistry, and pathology.

The headquarters building will contain a library of 600,000 volumes and an auditorium seating 1,500 people. A clinic will contain 600 beds and there will be almost one laboratory for every patient, allowing the maximum amount of attention to each case. Apart from the laboratories and clinic will be a section of apartment buildings to accommodate 12,000 people including 5,500 doctors, research workers, and nurses.

One of the ultra-modern features of the center will be a laboratory in which healthy patients may be subjected to the atmospheric conditions of various climates, ranging from the arctic to the

subtropics, while doctors study their reactions. Thus it will be possible to determine, theoretically at least, what diets are best in various climates for people engaged in various activities.

In the "clinic of healthy and sick man" scientists will determine the effect upon people in various states of health of working, eating, and sleeping.

Before drawing up plans for this ambitious center the All Union Institute of Experimental Medicine sent a commission to the United States to study the work of the medical centers at Cornell and Columbia and the Rockefeller Institute, and it is probable that a representative of the New York city health commission will visit Moscow next spring to give consultation.

While the Soviet Union is still greatly handicapped in the field of practical medicine by lack of capable physicians and of medical supplies this condition has not been allowed to retard progress in the province of experimental medicine.

The plans of the Soviet for the development of the system of "state medicine" are almost limitless and the new medical center will form an indispensable part of the system.

The buildings and the equipment, some of which may be bought in the United States, will cost about 150,000,000 rubles. The center should be in full operation by 1939.—*New York State J. Med.* 35, 4:156 (Feb. 15), 1935.

Specific Expenditures and Personnel of Official Health Agencies in Certain Cities*

JOSEPH W. MOUNTIN, M.D., F.A.P.H.A.

U. S. Public Health Service, Washington, D. C.

IN the first article of this series dealing with the work of the Sub-committee on Current Practices of Health Departments, attention was called to the lack of any central body of up-to-date information on the status and practices of state and local health departments. Suggestions were made regarding the types of data useful to health administrators which could be collected on an annual basis without undue effort and at very low cost. These suggestions were based very largely on the experience of the Sub-committee on Current Practices of Health Departments in dealing with the data compiled in connection with the Inter-city Health Conservation Contest for the years 1930, 1931, 1932, and 1933.

These data have proved to be very valuable in portraying changes taking place in city health departments during a period when the demands for read-

justment were unusually great. In the first article it was pointed out that appropriations were maintained very well through the year 1931. In 1932 many cities reported decreases in appropriations but, for the most part, the amounts were small and it was possible to maintain programs by minor adjustments in budgets. But in 1933 very drastic reductions were experienced by most cities, often resulting in serious disorganization of staff and curtailment of service.

The schedule used in the contest of 1933 for the first time made provision for obtaining data on personnel which can be compared with those reported by other agencies for previous years. Some of these data together with expenditures of health departments for specific services will now be considered.

EXPENDITURES BY FUNCTIONS

In attempting to allocate expenditures to functions, considerable difficulty was encountered. Definitions of services and fiscal practices of the health departments entered in the contest could not always be reconciled with each other. Not infrequently, one worker might be employed on two or more activities, and yet, the salary might be paid out of only one appropriation item. The following examples may be cited: The health officer may also be

* Second article based on Report of Sub-committee on Current Practices of Health Departments of the Committee on Administrative Practice. The author is Chairman and the other members are: E. L. Bishop, M.D., Louis I. Dublin, Ph.D., Allen W. Freeman, M.D., George T. Palmer, Dr.P.H., and John L. Rice, M.D.

The tables and references in this article have been numbered to follow consecutively those presented in the first article of the series, "A Central Information Service on Current Practices of Health Departments," Joseph W. Mountin, M.D., *American Journal of Public Health*, Mar., 1935.

TABLE IV

PER CAPITA IN CENTS AND PERCENTAGE DISTRIBUTION OF EXPENDITURES BY OFFICIAL AGENCIES FOR SPECIFIED HEALTH SERVICES * FOR THE YEAR 1933

<i>Activity</i>	<i>Number of Cities Reporting</i>	<i>Average Per Capita</i>	<i>Per Cent of Total</i>	<i>Minimum Per Capita</i>	<i>Maximum Per Capita</i>
Administration	53	5.72	8.55	1.7	28.2
Vital Statistics	46	1.50	2.24	0.4	11.8
General Sanitation	46	8.31	12.42	1.4	25.1
Food, Drugs, Milk	53	10.14	15.15	3.1	21.5
Child Health Supervision †	54	19.92	29.76	2.9	65.3
Communicable Disease	36	7.30	10.91	0.7	11.9
Tuberculosis	35	7.25	10.83	0.6	14.0
Venereal Disease	42	2.78	4.15	0.4	17.8
Laboratory	51	4.01	5.99	0.4	18.2

* Exclusive of hospitalization, institutional care, medical relief, garbage collection and disposal, and capital expenditures and deficits

† Board of Education expenditures included

chief of the bureau of communicable disease, but that function may not be carried on a specific appropriation; inspectors paid out of an appropriation for general sanitation may do some milk control work; in some cities operating expenses are considered administrative charges, while in other places such items are apportioned among the several bureaus. Either plan just described may be followed with regard to certain common services such as clerical assistance, communication and transportation, and minor repairs or replacements. The figures assembled on expenditures by services during 1933 nevertheless are presented since it is believed they at least indicate the manner in which funds are being allocated among functions. The Sub-committee on Current Practices of Health Departments is now developing definitions of services and methods of cost accounting which will make possible more detailed types of analyses in the future.

The wide variation between minimum and maximum expenditures for the several items of service may be due in part to the relative importance attached locally to them, but it is probable that these variations arise more often from lack of uniformity in definitions and

methods of accounting. The figures on administration particularly should be taken with considerable caution. In spite of instructions to reserve this item for the purely administrative functions of the health commissioner's office, it is believed to be weighted with operating expenses and perhaps with communicable disease control. In the smaller cities especially, the health officer may be chief of the bureau of communicable disease. The figures on communicable diseases, when given, especially by the large cities, perhaps represent true expenditures for that purpose. It is strange however that expenditures for this basic activity are reported less frequently than for any service except tuberculosis. Communicable disease control is probably included under administration by those cities failing to report expenditures specifically for that purpose. Some overlapping may exist between general sanitation and control of food, drugs, and milk, since there may be unified direction of these related services, or the field inspection may be performed by the same persons working on a generalized district basis. The figures given for vital statistics, venereal diseases, and laboratory are apt to represent absolute expenditures. Child

health supervision, tuberculosis, and communicable disease control are perhaps heavily weighted with public health nursing, but it seems quite probable that in many instances nursing has not been correctly distributed over these and other services in proportion to the time actually spent on each.

It was possible to separate the costs of nursing from the general public health program in the schedules submitted by 26 contest cities for the year 1933. The great majority of these cities reported expenditures for nursing ranging between 12 cents and 25 cents per capita. In 4 cities, the amount fell below 10 cents; one small city, however, reported the highest expenditure, 67.6 cents per capita. The per capita expenditures for nursing by cities in different population groups are shown in Table V.

the Committee on Administrative Practice. The figures are presented in Table VI. There has been an increase of approximately 10 cents per capita in the expenditures of 1933 as compared with those reported ten years previously. However, as pointed out in the first article of this series, there may have been some selection by the contest of cities with high expenditures. In comparing per capita expenditures of 1933 with 1923 fairly large increases will be noted for certain services while others remain constant or show some decline. Amounts for the support of tuberculosis, venereal diseases, and food, drugs, and milk control have been increased more than for other services. Slight gains are made by general sanitation and child health supervision, but administration, vital statistics, communicable disease

TABLE V
PER CAPITA EXPENDITURES FOR NURSING BY CITIES GROUPED ACCORDING TO POPULATION

Group	Number of Cities	1933 Per Capita Expenditure (Cents)
I. 500,000 and over	4	11.96
II. 250,000 to 500,000	4	9.02
III. 100,000 to 250,000	5	17.53
IV. 50,000 to 100,000	5	19.30
V. 20,000 to 50,000	4	15.60
VI. Under 20,000	4	19.77

The extremely low per capita expenditure reported by one city in Group I and the very high figure given by another city in Group IV seriously distort the combined expenditures for these two groups of cities. No reason can be assigned for the extremely low per capita figures for cities in Group II. It is not possible to express the average per capita expenditure of all cities with any great degree of accuracy since such a figure would be unduly influenced by the high percentage of the population in the large cities.

By selecting comparable cities it is possible to make rough comparisons of the expenditures reported by contest cities with expenditures reported in 1923 and with those recommended by

control and laboratory service sustained a slight loss.

The per capita expenditures of contest cities for general sanitation and the control of foods, drugs and milk approach the amounts given as adequate in *Community Health Organization*. The per capita expenditures for all other services are far below the standards recommended in the publication quoted.

By referring to Table VI it may be observed there is a striking similarity in the percentage distribution of the budget among the several items of service reported by contest cities and as given in *Public Health Bulletin 164* for the year 1923. In *Community Health Organization* it is recommended that a larger percentage of the budget be de-

† *Community Health Organization*, Table VIII, "Public Health Nursing," redistributed among other services according to Table III, "Bedside Care Excluded."

voted to child health supervision than was the actual practice in either 1923 or 1933. It must be understood however that the budget recommended in *Community Health Organization* is nearly 3 times what was actually available in either 1923 or 1933. Furthermore it is only after health departments have taken care of prescribed regulatory duties that consideration can be given to preventive activities having a large element of personal service and which are not as yet so well established.

PERSONNEL EMPLOYED

The schedule used in connection with the contest of 1933 made provisions for reporting the number of employees according to certain professional classes and time devoted to official duty. The employment of physicians, nurses, and engineers was selected as a criterion for determining the extent to which staffs have been professionalized, first because programs of practically all health departments embrace medical, nursing, and sanitation activities, and second because the educational requirements for ad-

HEALTH DEPARTMENT PERSONNEL PER 100,000 POPULATION FOR THE YEAR 1933 AS
REPORTED BY 68 CONTEST CITIES

Group	Number of Cities Reporting	Physicians		Nurses		Engineers		Others		Total	
		Full- Time	Part- Time	Full- Time	Part- Time	Full- Time	Part- Time	Full- Time	Part- Time	Full- Time	Part- Time
I.	9	1.95	4.86	13.86	1.26	0.28	0.04	16.09	2.05	32.18	8.21
II.	13	1.52	3.37	7.54	0.07	0.07	0.00	14.80	0.34	23.93	3.78
III.	17	1.74	3.97	7.76	0.52	0.26	0.04	17.21	0.96	26.97	5.49
IV.	16	1.45	8.70	9.28	0.29	0.19	0.10	14.31	2.32	25.23	11.41
V.	13	1.60	5.25	7.30	2.05	0.00	0.46	11.18	3.19	20.08	10.95

mission to these professional classes are fairly well established. The number of cities employing full-time and part-time personnel is given in Table VII. It may be noted that of the 68 cities supplying data satisfactory for analysis, 51 employ full-time physicians, 64 full-time nurses, and 13 full-time engineers. Nursing service for the most part appears to have been put on a full-time basis. More than half the cities in Group V rely exclusively on part-time physicians, and presumably the same cities employ part-time health officers. Sanitation, a well established and basic activity of health departments, apparently continues on a non-professional basis in the majority of cities since only 13 of the 68 cities employ full-time engineers. The information on cities in Group VI was not satisfactory for analytical purposes.

The number of employees in relation to a definite unit of population is given in Table VIII. A unit of 100,000 population is taken as a base in order to compare the contest figures with those of other studies. The larger cities, as may

be judged from these figures, employ the greatest number of both professional and non-professional people. There is a striking similarity in the numbers of full-time physicians and nurses employed by cities falling into Groups II, III, IV, and V. The smaller cities apparently favor the employment of part-time personnel more than do the cities in the larger population groups. This table also shows the lack in professional direction of sanitation as indicated by a low ratio of engineers to the population.

The classification of personnel used in *Public Health Bulletin 164* differs in many respects from that used for the contest cities. It is possible however to make direct comparisons between the number of physicians, nurses, and total employees in the cities falling into Groups I, II, and III. This is done in Table IX.

According to the data presented in Table IX, there has been some increase in the total number of employees by cities of Groups I and III for the year 1933 as compared with 1923. The most

TABLE IX

NUMBER OF PHYSICIANS, NURSES AND TOTAL EMPLOYEES PER 100,000 POPULATION
IN CONTEST CITIES AND CITIES REPORTED IN *Bulletin 164*

Group	Contest Cities						Cities Listed in Bulletin 164					
	Physicians		Nurses		Total Employees		Physicians		Nurses		Total Employees	
	Full- Time	Part- Time	Full- Time	Part- Time	Full- Time	Part- Time	Full- Time	Part- Time	Full- Time	Part- Time	Full- Time	Part- Time
I..	1.95	4.86	13.86	1.26	32.18	8.21	0.62	5.26	8.02	0.00	21.01	6.52
II..	1.52	3.37	7.54	0.07	23.93	3.78	0.93	5.11	6.67	0.00	23.60	5.44
III..	1.74	3.97	7.76	0.52	26.97	5.49	0.89	4.31	6.47	0.00	20.97	5.38

significant figures are believed to be those regarding the increase of full-time physicians in the contest cities of all three groups, first on account of the relative size of the increase, and second because physicians are apt to be employed in positions of responsibility. The increase in the number of full-time nurses also is encouraging although the relative gain is not so great as that reported for full-time physicians. Unfortunately comparative figures on engineers for 1923 were not available.

SUMMARY

An analysis of the data made available through the Inter-city Health Conservation Contest shows a wide variation between maximum and minimum expenditures for specific activities by official health agencies in cities. For example, the per capita expenditure for child health supervision ranges from 65.3 cents to a low point of 2.9 cents; communicable disease control from 11.9 cents to 0.7 cent, and administration from 28.2 cents to 1.7 cents. It is probable that some of the variation in

expenditures arises from a lack of uniformity in definitions of services and methods of accounting. The Subcommittee on Current Health Department Practices is developing definitions for services and methods of cost accounting which will make possible a more satisfactory type of analysis than can be made with data available at the present time.

An analysis of health department personnel indicates that the larger cities employ the greatest number of workers per 100,000 population. A comparison of the 1933 figures with those of 1923 shows a decided increase in the number of full-time physicians employed. Sanitation still consumes a large part of the budget of municipal health departments but this important service, with comparatively few exceptions, has not been placed under the direction of graduate engineers.

Health Exhibits

THERE are several famous health museums in foreign countries. There were none of note in this country till November, 1934. During that month a movement to give America its own museum of hygiene got under way in Chicago.

With but one exception (a foreign exhibit) all medical and health exhibits of the Century of Progress will be placed permanently in the large Rosenwald Museum. It should become a factor in teaching health.—*California & West. Med.* 42, 2:129 (Feb.), 1935.

Trend in Public Health Nursing*

PEARL McIVER, R.N., F.A.P.H.A. (*Life Member*)

*Associate Public Health Nursing Analyst, U. S. Public Health Service,
Washington, D. C.*

THE public health nursing movement in the United States is approximately 50 years old. Its growth has been rapid, especially during the past 20 years. When the National Organization for Public Health Nursing was organized in 1912, there were only 3,000 public health nurses in the United States. Today, there are approximately 20,000 public health nurses. But in spite of this tremendous increase, there is a distinct need for more public health nursing service in both rural and urban areas of practically every section of the country.

CHARACTERISTIC TREND AT PRESENT TIME

The most characteristic trend in the present public health nursing movement is the tendency toward a critical self analysis—a desire to evaluate the past and present public health nursing practices and accomplishments in terms of proven value. At no time in the history of public health nursing has there been as much available material as there is at present.

The survey conducted by the N.O.P.H.N.¹ gives an excellent picture of a cross-section of average public health nursing practice in both official and nonofficial agencies, in rural and

urban areas, from the east, west, north, and south sections of the country.

The Nursing Studies Division of the Milbank Memorial Fund² has given us some excellent detailed analyses of nursing in three selected health organizations, a county health department, a medium sized city health department, and a district of a large city health department. These studies are especially valuable in determining the effect of generally accepted practices and in helping to plan an economic distribution of nursing time.

The U. S. Public Health Service, through its studies of public health administrative methods, is prepared to give an accurate picture of the distribution and nature of the nursing service in a number of county health departments. These are, especially significant because they have been carried on concurrently with studies of the work of the health officers and sanitary officers, and it will therefore be possible to show how public health nursing work is correlated with all of the other public health activities of the community.³

Under the direction of Teachers College, Columbia University, New York, the writer was privileged to make an analysis of public health nursing in 10 selected health organizations. This study differs from the others mentioned in that a definite effort was made to include only "superior" public health organizations and the most successful nurses employed by those organizations.

* Read before the Health Officers Section of the American Public Health Association at the Sixty-third Annual Meeting in Pasadena, Calif., September 4, 1934.

The findings are especially interesting when compared with the findings of the N.O.P.H.N. survey which represents average practice.⁴

There are also numerous less intensive surveys and analyses of public health nursing services in local areas, but those mentioned are sufficient to show that public health nurses are concerned with the analysis of their own progress and accomplishments. The first step toward increased accomplishments is the recognition of weaknesses in past practices, and a conscientious effort to promulgate those which have been productive, and to eliminate or modify those which have not produced desirable results. Consequently, some of the traditional conceptions of public health nursing are undergoing changes.

INSTANCES WHICH APPEAR TO INDICATE A CHANGING CONCEPTION OF PUBLIC HEALTH NURSING

1. There has been a shift in emphasis from the private to the official public health nursing agency. Public health nursing was initiated and largely developed by the private or nonofficial agency. The private agency was the leader in developing standards and in improving practice for many years. Recent surveys show that a greater number of nurses are now employed by official than by nonofficial agencies and that the official agency in many sections of the country is assuming leadership in the promotion of public health nursing.

2. There is a tendency toward an amalgamation of public health nursing agencies. Since public health nursing was initiated and largely developed by the private agencies, it is not surprising to find still a multiplicity of agencies in some communities. Therefore, the N.O.P.H.N. Survey Committee recommends that an effort be made to combine nursing agencies, that there never be more than two public health nursing

agencies, one official and one nonofficial, in any community, and that experiments be made in rural and small urban areas with but one agency responsible for all public health nursing work.

3. Community needs are being recognized as the keynote in planning public health nursing programs. Many such programs have in the past been based upon "agency facilities" instead of community needs. A tuberculosis program was planned because the community had some "Seal Sale" money; a school inspection program was undertaken because the nurse liked to do that type of work; or an infant hygiene program was instituted because the largest contributor was primarily interested in babies. Each agency appeared to be satisfied with its own special program and only incidentally concerned with the other health problems in the community. This procedure is still common in many communities, but there is a trend toward community planning from broader aspects which is significant.

4. Official as well as nonofficial agencies must recognize the importance of citizen participation in the public health program. Health councils and central planning committees are essential elements in the successful operation of any public health program. The N.O.P.H.N. survey showed that official agencies in particular have not made as much progress in this direction as is desirable. As stated, there is need for considerably more public health nursing service than is now available. Adequate financial support is dependent upon the wholehearted endorsement of the receiving public. The need for citizen participation in the promotion of private public health nursing agencies has long been acknowledged. It is being recognized as equally essential to the official public health nursing agency.

5. The quality of the performance of nurses in certain phases of the generally accepted public health nursing

program is quite unsatisfactory. For years we have glibly spoken of the public health nurse as a teacher. The interpretation of the medical, sanitary, and social procedures has been listed as her greatest contribution. In determining quality of performance, the N.O.P.H.N. Survey Committee rated every nursing visit observed on 4 factors:

1. Approach—The ability to meet people, to establish a friendly relationship, and to adjust to various situations.

2. Nursing technic, her understanding of the underlying principles, the relative importance of the various steps of her technic to the well-being of the patient.

3. The adequacy of the care given. Was everything that was indicated done for the patient upon that visit?

4. The teaching, both direct and indirect. Did the nurse recognize opportunities for teaching? was her instruction accurate? and was it suited to the needs of those who were instructed?

Considering these 4 factors—approach, technic, adequacy of care, and teaching—it was a severe jolt to many of us to find that teaching received the lowest rating for all types of organizations and for all types of service. Approach was rated highest in every case. It is, therefore, quite evident that the majority of our nurses are not well qualified to do that which is considered one of the most important features of their work, namely, teaching of health.

6. There is a change in the meaning of the term "educational work." Many official organizations have stated emphatically that their nurses do "educational work" only, meaning that they give no nursing care. The modern school teacher has long since given up the idea that her teaching will be effective if it is "by word of mouth" only. The nurse who thinks she can tell a mother how to care for a typhoid fever patient as effectively as she can demonstrate that technic, is out of date. Likewise, the public health nurse who gives nursing care to the typhoid fever pa-

tient and does not explain each step of the procedure to the mother or other attendant, or who continues to give that care after the attendant has learned how to do it correctly, is equally inefficient. However, service is a valuable partner to advice, and real "educational work" demands both. Is it not probable that the tendency on the part of some of the official relief agencies to set up public health nursing programs, independent of the existing health authorities, may be traced to the failure of the health departments to recognize the educational value of nursing service?

RECOMMENDATIONS IN REGARD TO FUTURE DEVELOPMENTS IN PUBLIC HEALTH NURSING

1. If the emphasis is to be shifted from the private to the official public health nursing agency, departments of health must be awake to their opportunities and be willing to assume the responsibility for leadership. Some public health officials are of the opinion that the rendering of nursing care to the sick is not a legitimate public health function, and as a consequence, they have completely excluded it from their programs. Good nursing care in acute illnesses and for maternity cases is an important factor in saving lives and in improving the health of hundreds of citizens in every community every year. Private duty nursing will never solve the problem, especially in rural or small urban areas. Some other provision must be made for indigent families and for those families who are not classed as indigent, but who have limited financial resources. If there is to be an amalgamation of public health nursing agencies, and if the official agency is to assume the entire responsibility for public health nursing work, especially in rural areas, health commissioners must be cognizant of all of the health needs of the people in their communities and be willing to help to meet those needs.

Our definition of public health functions must be broad enough to meet the health needs of the people or it will become necessary for other agencies to establish public health nursing programs.

2. In the past, public health nursing was frequently developed as a separate entity. Nursing leaders now recognize that it should be developed as an integral part of the entire community public health program. The successful public health nurse, who has been adequately prepared for her job, is an ideal interpreter of medical, sanitary, and social procedures. She is as much a help to the sanitary engineer and the social welfare worker as she is to the medical officer in keeping them informed regarding conditions she finds in the homes and schools and in interpreting their specialties to the families. Therefore, public health nursing should not be considered the prerogative of any medical specialty, such as child hygiene or tuberculosis control. The services of the public health nurse should be available to every division of the health department in accordance with the needs of those various divisions. Administratively, the nursing personnel, through a supervisor or director from their own ranks, should be directly responsible to the health commissioner or medical director. Thus the nursing service will become integrated throughout the entire public health program and the greatest good will be rendered to the greatest number.

3. We have not always given enough consideration to community needs and community desires in planning the public health program. In some of the more technical aspects of public health administration, such as safeguarding the public water supply, the public's need may be in opposition to the public's desires. The people may object to the taste of chlorine in the water and clamor for the kind of water they

formerly had. Health *needs* must, of course, be the deciding factor in such a controversy. However, except in emergencies when a delay in carrying out certain procedures might endanger many lives, the desires or "felt needs" of the people may be used as the basis for the introduction of more fundamental control procedures. It should be the aim of the health administrator to be thoroughly familiar with all of the health needs of the community and to encourage a better understanding of scientific public health procedures by relating those procedures to the recognized needs and common desires of the people.

4. Citizen participation in the health program, through health councils and planning committees, naturally follows. While mortality and morbidity records may be the more reliable index of community needs, the desires of the people as expressed by a representative group of laymen may often be a more sensitive index of real community needs. There was given before the Nursing Section of the American Public Health Association at Indianapolis last fall, an excellent paper on lay participation in a health program,⁵ in which were described the 3 steps or stages in successful lay coöperation. (1) learning about the health problems and what is being done to solve those problems; (2) participation through rendering volunteer service; (3) serving on advisory or planning committees. No one can be of any real value in the third capacity unless he has passed through the first 2 stages. I have found that these same steps are very valuable in securing the support of the practising medical profession. The country doctor may know very little about public health nursing and actually believe that he does not want to know much about it.

My experience in the promotion of rural public health nursing taught me to begin by visiting the doctor and

listening to his problems. Gradually, I would tell him about the functions of a public health nurse, and later, ask him to help me; not that his hurried inspection of 50 children in an hour really meant much, but because I wanted his advice on community health problems. I knew that the surest way to get him to consider those problems and to give me his advice was to get him interested through volunteer service. During the depression, many agencies depended upon volunteers for services usually performed by their staffs. The result has been that the accomplishment of the staff has increased considerably through being relieved of many non-professional functions, and the public's interest in the service has increased accordingly.

5. The N.O.P.H.N. survey has proved to us that there is much to be desired in the quality of the performance of the average public health nurse. Her teaching ability is limited, and her nursing technic is quite frequently unsatisfactory. Fortunately, there are a limited number of excellent public health nurses who are splendid teachers and who carry out the same perfect technic in the homes which they were taught in the hospitals, easily and habitually.

The writer's study of "best" public health nursing practices gives numerous illustrations of excellent teaching and faultless technic. The N.O.P.H.N. survey has proved that that quality of work is the exception rather than the rule throughout the country. What then must be done to improve the quality of public health nursing work? The first step appears to be the definition and the establishment of regulations concerning the qualifications of public health nurses. The N.O.P.H.N. and the Committee on Personnel Qualifications of the American Public Health Association have adopted the same minimum requirements. These require-

ments are *minimum*—not *maximum*. Most of the 10 organizations included in the writer's study of best public health nursing practices had much higher requirements than these, yet, only a very small percentage of the agencies included in the N.O.P.H.N. survey had any special requirements other than registration as a graduate nurse. Public health nursing is a specialty, and graduation from a 3 year course in a school of nursing does not prepare a nurse to do efficient public health work.

The provisions of personnel regulations are not retroactive and do not, as a rule, apply to persons who are "on the job." Our next problem is, then, what to do with the mass of nurses who are now doing public health work but who are not adequately prepared for their jobs. First, the nurses should be encouraged to take advantage of extension work in public health nursing and the allied subjects when such opportunities are available; (2) health administrators should make every effort to relieve nurses who desire to improve themselves through summer courses, and should encourage others to follow this example; (3) adequate nursing supervision should be provided for every public health nurse.

The N.O.P.H.N. survey found that quality of performance was positively correlated with the amount and quality of the nursing supervision provided. Twenty-three per cent of the agencies included in the survey provided no nursing supervision for their staff nurses. Good supervision implies a good staff educational program. Even the well prepared public health nurse needs to be continually improving herself or she will get into a rut and the quality of her service will deteriorate. Good supervision keeps the staff nurse interested and enthusiastic in her work, eager to use her own initiative and alert to improve her own practices. It makes the staff nurse feel

that her best work has been appreciated and that anything less than her best efforts are not worthy of her. Nursing supervision of that type will yield good returns in the improvement of the quality of performance.

May I repeat the 6 recommendations concerning the future development of public health nursing in the United States?

1. Increase the leadership from the official health agencies and enrich the nursing programs offered by official agencies.

2. Experiment with the amalgamation of nursing agencies with the idea of placing all public health nursing service under one agency in rural and small urban districts, but with the complete utilization of all community resources.

3. Develop public health nursing as an integral part of the whole community health program, not as an entity in itself nor as a subsidiary of any one medical specialty.

4. Emphasize the importance of considering community needs and community desires as the basis for program planning.

5. Increase citizen participation in the entire public health program.

6. Improve the quality of Public Health Nursing—first, through clearly defining and rigidly enforcing minimum qualifications for public health nurses, and, second, through providing a sufficient amount and a high quality of nursing supervision.

Hospital Morbidity Statistics

THE appearance of *Standard Classified Nomenclature of Disease* prompts Bolduan to revive his suggestion originally published in 1913, that hospital morbidity statistics should be classified, tabulated, and studied more extensively as a source of information concerning non-fatal and non-communicable diseases. His proposal is that coöperating hospitals should send "discharge certificates" to a central recording agency, on discharge of all patients these certificates specifying such items as age, sex, race, social condition, occupation, period of hospitalization, disease, complications, operations, etc. The data would be transferred at the central agency to punch cards, mechanically tabulated, and analyzed. It is held that the resulting information would be of value to hospital authorities as a guide in planning hospital facilities, and in evaluating medical and surgical

policies. Health authorities might obtain through such data, information concerning non-communicable morbidity, that would point the way to more efficient preventive measures. The need of such information is obvious. Inquiry is highly desirable to determine the degree to which hospital populations can throw light upon the health problems of the general population.

In 1933, the Minnesota Hospital Association approved a project along these lines on the proposal of Dr. H. L. Dunn, Director of the University Hospitals, Minneapolis. *Minnesota Journal—Lancet*, 54, 6:148-157 (Mar. 15), 1934). No doubt, experiments along these lines have been undertaken in other places.—C. F. Bolduan. *Hospital Morbidity Statistics*. Reprint series. Health Dept. New York City. 2nd ptg. 1934. See also editorial in *J.A.M.A.*, 104, 7:565 (Feb. 16), 1935.

Laboratory Examinations of Milk Handlers*

EARLE K. BORMAN, D. EVELYN WEST, AND
FRIEND LEE MICKLE, F.A.P.H.A.

*Assistant Director; Chief Microbiologist; and Director, Bureau of Laboratories,
State Department of Health, Hartford, Conn.*

BEFORE entering into the discussion of problems associated with the laboratory examination of milk handler specimens, we should fix firmly in our minds those factors associated with the production of milk which operate from time to time to produce milk-borne diseases, together with the epidemiological importance of these infections.

There are two important factors upon which the existence of milk-borne disease depends: (1) The presence of such diseases as bovine tuberculosis, *Brucella* infection, and certain types of mastitis in the dairy herd; and (2) the presence of carriers and cases of infectious disease among milk handlers. Instances of a milk supply becoming contaminated with pathogenic microorganisms by other means have been recorded, but in general these have not been of importance in the history of milk-borne disease. In discussing the problem at hand we are only indirectly concerned with the first factor although the laboratory has played a large part and will undoubtedly continue to play an even larger part in the campaign to eradicate diseases spread in this fashion.

Between 1880 and the end of 1933, 1,032 milk-borne outbreaks† of disease traced to human carriers and cases have

been reported in the United States. Among these are included outbreaks of septic sore throat caused by contamination of the milk with beta hemolytic streptococci from diseased udders since these organisms have most probably been transmitted to the dairy cattle by milkers. These outbreaks have involved 53,582 known cases with 1,045 known deaths. Undoubtedly, there have been many other outbreaks which did not come to the attention of health authorities. It is interesting to compare the number of these outbreaks occurring before 1910 with those occurring after. Only 272 outbreaks, 26.4 per cent of the total, are recorded before 1910, as compared with 760, 73.6 per cent of the total, between 1910 and 1933. This is undoubtedly due to a number of factors associated with increased public health activities, increased milk production, and the increase in milk consumers as a result of increasing population and education in nutrition. In this discussion we shall consider the statistics for the period 1910 to 1933 as the most reliable indication of the actual prevalence of milk-borne disease. A summary of the outbreaks traceable directly or indirectly to human contact with the milk during this period is given in Table I.

* Read at a Joint Session of the California Association of Dairy and Milk Inspectors and the Laboratory Section of the American Public Health Association at the Sixty-third Annual Meeting in Pasadena, Calif., September 6, 1934.

† We are indebted to Leslie C. Frank of the U. S. Public Health Service for data on milk-borne outbreaks furnished this department.

TABLE I

<i>Disease</i>	<i>Number of Outbreaks</i>	<i>Number of Known Cases</i>	<i>Number of Known Deaths</i>
Typhoid Fever	574	8,459	406
Septic Sore Throat	81	26,773	226
Scarlet Fever	72	5,326	40
Diphtheria	33	1,083	11

Typhoid fever is the most prevalent outbreak caused by carriers or mild cases on a milk supply and diphtheria the least. Streptococcus infections, such as septic sore throat and scarlet fever, occupy an intermediate position. The average streptococcus outbreak has caused approximately 210 cases of disease as compared with approximately 15 cases in each outbreak of typhoid fever during the same time. There have been approximately 7 known deaths associated with every 10 outbreaks of milk-borne typhoid as compared with 17 in every 10 outbreaks of the streptococcus infections. The death rate per outbreak is almost twice as great for the streptococcus infections as for typhoid fever. There have been almost 4 times as many cases associated with streptococcus infections as there have been of typhoid (32,009 cases of streptococcus infections as against 8,459 cases of typhoid fever).

Comparative statistics for Connecticut are available from 1918 through 1933. During that time Connecticut had 19 outbreaks of typhoid and paratyphoid fevers traced to milk, with 256 known cases, while no outbreaks of milk-borne diphtheria occurred. Twelve milk-borne outbreaks of septic sore throat and scarlet fever occurred, resulting in 1,042 cases. The total number of cases of typhoid and paratyphoid fevers from all sources reported in Connecticut during this time was 4,106; of septic sore throat and scarlet fever, 52,530 (1,581 of the former, 51,949 of the latter). Thus, milk was the vector in 6.2 per cent of all cases of typhoid and para-

typhoid fevers, in 36 per cent of the septic sore throat cases reported and in 0.9 per cent of the scarlet fever cases. Of the combined number of cases of the two streptococcus infections 2 per cent were traced to milk. With 1 exception, all milk-borne outbreaks of disease have been traced to ungraded raw milk which is not subject to any regulation in regard to physical or laboratory examinations of milk handlers.

From these figures no one can doubt the urgent necessity for remedial measures designed to control and eradicate outbreaks of milk-borne infections, especially after having witnessed the demoralizing explosiveness with which a community may be stricken. It is recognized that efficient pasteurization of the milk supply, coupled with proper precautions to prevent its subsequent contamination, is the ultimate solution. However, the introduction of 100 per cent pasteurization on a state-wide basis is at present a very remote possibility in most states. Even pasteurized supplies need attention from health authorities. The potential menace of the presence of a carrier in a pasteurizing plant has been repeatedly demonstrated. A striking example is the outbreak in San Francisco in 1928. Educational methods have a place in the program for the elimination of carriers, but it would be foolhardy to expect the elimination of milk-borne outbreaks by that means alone. For these reasons, the State of Connecticut has resorted to periodic physical examinations of milk handlers supplemented at each examination by routine laboratory tests with considerable success in locating carriers and cases.

The Connecticut program was initiated to bring the joint efforts of medical and laboratory science to bear upon the source of the majority of outbreaks of milk-borne disease, *i.e.*, upon milk handlers who are carriers or cases, by

insisting that each handler of certain grades of milk be given periodic physical examinations by a licensed physician, and that this physician consider certain laboratory tests performed in an approved laboratory an integral part of his examination before certifying his opinion of fitness to handle milk. Experience has dictated certain changes in the requirements since 1927 and, in all probability, further changes will be made as necessity demands. We wish to emphasize that Connecticut requirements have been designed to give the maximum protection possible with available facilities under Connecticut conditions.

COST OF THE CONNECTICUT PROGRAM

In a previous publication¹ Connecticut requirements for periodic laboratory examinations of milk handler specimens and the laboratory methods involved were briefly described. The results obtained in 91,257 laboratory examinations over a period of 6 years and 5 months were reported. The cost of these tests to the state was estimated at \$48,000, making the average cost of detecting each of the 71 carriers found \$677. These figures were obtained by utilizing the average cost of an examination of any type made in these laboratories for the several years under study. It was pointed out that the estimated cost was considerably in excess of the actual cost, since many other types of examinations made were

more consuming of time and material than those on milk handler specimens. A study of the actual cost of this activity for 1933, when 24,487 examinations were made on milk handlers, has confirmed this viewpoint. This cost-survey has taken into consideration the amounts expended for salaries, materials, and overhead, plus a figure apportioned to this activity for depreciation of equipment, all summarized in Table II. The salary cost and the cost of materials are very nearly exact for this phase of our activities. The overhead and depreciation charges are probably high since these have been apportioned among various phases of the work of the laboratories by using the ratio of the number of examinations of this type to the total for the entire organization. The cost of making 24,487 examinations of this type in 1933 was \$7,966 and the average cost per examination on milk handler specimens was 32.5 cents. This figure is approximately two-thirds as great as that estimated on a different basis in the previous study. It is a reasonable assumption that this ratio between actual costs and those previously estimated has applied throughout the entire period during which periodic examinations on milk handler specimens have been made. This would reduce the amount expended on the 91,257 examinations between April, 1927, and August, 1933, to about \$35,000 instead of the \$48,000 previously estimated, and would make the

TABLE II

COST OF MAKING 24,487 LABORATORY EXAMINATIONS ON MILK HANDLERS IN 1933

<i>Itemized Cost</i>	<i>Laboratory Work Proper</i>	<i>Outfit Work</i>	<i>Wash-up and Sterilizing Work</i>	<i>Receiving, Reporting, and Records</i>	<i>Laboratory Administrative Work</i>	<i>Total for All Laboratory Activities</i>
Salaries	\$3,509	\$152	\$456	\$1,421	\$103	\$5,641
Materials	300	280	50	400	...	1,030
Overhead	620	60	180	240	...	1,100
Depreciation	120	10	55	10	...	195
Total Cost	\$4,549	\$502	\$741	\$2,071	\$103	\$7,966

unit cost per carrier for this period \$464 as compared with \$677.

SUMMARY OF REPLIES TO THE MILK HANDLER QUESTIONNAIRE

The conflicting opinions of public health officials on this subject and the interest in control of food handlers induced us to seek the opinions of public health laboratory directors, other health officials, and university professors of public health and bacteriology, in this country and elsewhere, on periodic laboratory examinations of milk handlers in general and on the methods employed in Connecticut in particular. A questionnaire was sent to 205 individuals.

A majority of those who replied believe that routine laboratory examinations of milk handler specimens constitute a desirable adjunct to any program for the control of milk-borne disease. The main differences of opinion were in regard to the types of laboratory examinations desirable.

A number stated they feel routine, periodic examinations have a distinct educational value in demonstrating to milk handlers and producers the source of much milk-borne disease and the manner in which disease germs may be introduced into milk.

Of the 66 individuals expressing an opinion in regard to whether or not the routine laboratory examination of specimens from milk handlers as performed in Connecticut is a sufficiently worthwhile procedure to justify the cost (as previously estimated), 43 felt it a worthwhile procedure, while 23 took the opposite view. The objections were as follows:

1. The procedure gives a false sense of security.
2. The rapidity of turnover in employees makes enforcement difficult.
3. The cost is too great in comparison with results obtained.
4. Pasteurization of the milk supply is a much better and more inexpensive means of attaining the same end.

5. Laboratory examinations should be made only when the physical examination, the employee's past history, or the epidemiological evidence warrants taking specimens of a particular kind.

6. The intermittency of the carrier state lessens the value of any one examination.

A number of those who favored discontinuation objected only to one or more of the tests required in Connecticut, particularly sputum for *Mycobacterium tuberculosis*, the Widal test as an aid in detecting typhoid carriers, and the throat and nose cultures for beta hemolytic streptococci. Only 4 persons out of 65 felt that this routine activity had no value whatsoever regardless of its cost. Fifty out of 55 felt that the use of this procedure must necessarily depend on the locality or the appropriation available and that the examination should be undertaken or not depending upon circumstances.

DISCUSSION OF REPLIES

In discussing the opinions advanced by others we must of necessity examine them in the light of practical experience in Connecticut, and for that reason the conclusions reached may be applicable only to localities where conditions are similar to those under which this procedure has been initiated and developed.

In general, the criticisms of the Connecticut program are from 3 viewpoints—the administrative, the economic, and the scientific.

From the administrative viewpoint some have objected that the use of routine laboratory examinations gives a false sense of security. However, we must not lose sight of the fact that these examinations are not made the sole basis for issuing a health certificate. The certification is made by a licensed physician after physical examination of the milk handler. The laboratory examinations are merely a compulsory, routine part of the physical examination, and the results are reported only

to the examining physician and the local health officer involved. In fact, the examining physician is merely required to certify that the employee is not suffering from any communicable disease at the time of the examination. Milk handlers reported as suffering from communicable diseases between examinations are subject to the requirements of the Sanitary Code ² before returning to their occupation.

From an administrative viewpoint, some have expressed their belief that the turnover among any group of food handlers is too great to permit satisfactory supervision. Our experience is that the turnover among milk handlers in Connecticut is so small that the objection does not have much weight in this state, although doubtless among certain other groups of food handlers, such as restaurant employees, the turnover is normally too great for the application of a similar program.

From the economic viewpoint, some have expressed the opinion that the cost is too great. The cost of the physical examinations is borne by the employers and as yet has not brought about any increase in the cost of milk, so this discussion must be confined to the laboratory tests. Our reported estimates ¹ were stated to be considerably higher than the actual cost, and the more recent cost-survey now reported has shown that the previous estimates were approximately one-third too high. There is no way of determining the value of the results of the program in dollars and cents since we cannot estimate the number of cases of milk-borne disease prevented. However, we wish to reaffirm our position—that examinations of this type can be made in a central laboratory doing a large volume of work at a small average cost per examination (32.5 cents in these laboratories in 1933).

Usually those who maintain that the cost is prohibitive advance the sugges-

tion that pasteurization is the best solution. However, certain practical difficulties make its application impossible at this time throughout most large territories of mixed urban and rural communities. Pasteurization, properly done, is one of the greatest aids to public health officials in reducing disease hazards, but its application has been, and will continue to be, a matter of slow growth furthered almost entirely by educational methods and constantly checked by economic and political forces and misguided prejudices in any community. It is pertinent that a preliminary study of bottled pasteurized milk as delivered to the consumer in Connecticut indicates a decided need for more adequate control from a sanitary standpoint. Using the presumptive test ³ for the *Escherichia-aerobacter* group in the brilliant-green bile medium recommended by McCrady and Archambault,⁴ we have examined 499 samples from 144 pasteurization plants and have obtained positive results in 141 samples from 69 plants. If this may be taken as an indication that more than 28 per cent of samples from 48 per cent of the pasteurization plants included in the study are not thoroughly pasteurized or are contaminated after pasteurization, it would seem necessary to take every possible precaution to prevent occurrences similar to the San Francisco epidemic of 1928 by eliminating the carriers.

The great majority of health officials feel that laboratory examinations should be made if there is any indication that a milk handler may be a carrier of disease when either the physical examination or a history suggestive of past infection suggests the advisability of this procedure. Many feel the laboratory should be used only in this manner. Certain obvious questions must be raised and satisfactory answers provided before the value of the program they suggest can be determined. Under a program

where submission of specimens for laboratory examination is left to the discretion of the examining physician, is it necessary for some responsible central authority to select a group of physicians specifically for the purpose of giving physical examinations to milk handlers in order that the scope and thoroughness of the examination given be rigidly supervised or can the decision be left to the physician employed by the producer, with no more than advisory help from health officials? Can we depend upon the history of past infection gathered from statements made by the person being examined to detect those individuals most likely to be carriers of certain types of organisms? The average milk handler can give only a fragmentary account of past illnesses, and very often his memory does not extend back to childhood, from which time the carrier condition may have existed. Typhoid infection may be so mild that the individual may not have been aware of the nature of his illness. Furthermore, there is a tendency for many individuals to conceal pertinent facts from the examining physician for fear of not being allowed to follow a favored occupation.

It is not within the scope of this paper to discuss this particular type of program from an administrative viewpoint. To the best of our knowledge all but one of the carriers discovered among milk handlers in Connecticut in the past 7 years have been detected purely because laboratory examinations were required, and not as a result of the physical examinations or from a review of each individual's history of past infection.

Some authorities apparently feel the laboratory should be used only to aid in establishing the source of outbreaks. We admit that carriers are more readily and cheaply detected from individuals selected during epidemiological studies, but must point out that this is not a saving in the final analysis. If the car-

rier can possibly be detected before causing an outbreak, no loss occurs. If not, the public must stand the economic loss of the outbreak and, in many instances, new carriers are developed and the vicious cycle repeated in multiple. Our experience suggests that certain laboratory examinations should be made a routine part of the physical examination of a milk handler if we are to attain an acceptable efficiency in detecting carriers and removing them from contact with the milk.

A number of persons have set forth the shortcomings of the Connecticut program from a scientific angle. Chief among these is the fact that the carrier state is often intermittent or transient, and sometimes difficult to detect when required specimens are spaced at long intervals. This is a valuable criticism of the efficiency of the program, but in no way invalidates the results which can be and have been obtained under the circumstances. Answers to the questionnaire have also raised numerous questions in regard to the scientific value of certain of the tests required. These can best be discussed by treating each one separately.

Sputum for Tuberculosis—Forty-two of the replies to the questionnaire were in favor of continuing the examination of sputum for *Mycobacterium tuberculosis*; 19 were in favor of discontinuing it. The principal objections to this examination were: (1) A satisfactory physical examination should locate cases of tuberculosis before a positive sputum can be obtained. (2) Epidemiological evidence does not indicate that tuberculosis is at all frequently disseminated through handling of any food material by a tuberculous patient. On the other hand, some felt this is a valuable procedure since it provides a means of detecting open cases of tuberculosis in a representative group of individuals on a state-wide basis. It is well to consider here that the detection of an open

case of tuberculosis in a milk handler is perhaps more important from the standpoint of his contact with other dairy workers, and especially with his own family, than from that of his spreading the infection through contamination of the milk. As shown in our previous study, the practical results from the application of this routine procedure have been the detection of 7 open cases of tuberculosis among milk handlers in 6½ years. In all these instances, investigation has brought forth the opinion that the lesions were small ones, not readily detectable by physical examination, and that in all probability the number of organisms being thrown off in the sputum was minimal.

Throat Cultures for Virulent Diphtheria Organisms—Forty-eight individuals out of 64 answering this portion of the questionnaire were in favor of continuation of cultures from the throat for virulent diphtheria organisms. Those who favored discontinuing this examination pointed out the following facts: (1) Carriers of diphtheria organisms are quite frequently of the intermittent type and in many instances the carrier condition is very transient so that examinations have to be made too frequently to be practicable if all carriers are to be detected. (2) Milk-borne outbreaks of diphtheria are relatively rare, and their occurrence is becoming even more rare. (3) Immunization of the susceptibles in any given population can be obtained at a relatively small cost. However, persistent carriers of diphtheria organisms have been encountered in the work of nearly every experienced laboratory worker and these should be given particular attention in framing a milk handler control program.

Nose Cultures for Virulent Diphtheria Organisms—Forty-three out of 62 were in favor of continuing the making of nose cultures for diphtheria organisms. These cultures were discussed along the

same lines as throat cultures but some felt that the making of nose cultures as well as throat cultures was an unnecessary duplication of effort. Bartlett and Bransfield,⁵ however, have shown that nose cultures are as important as throat cultures if all carriers are to be detected.

Feces for Typhoid and Paratyphoid Organisms—Sixty-one were in favor of continuing the examination of feces specimens for typhoid and paratyphoid organisms; 5 were in favor of discontinuing this examination. Those in favor of discontinuing pointed out the intermittency of the carrier state or said that they felt these examinations should be made only when history of past infection indicates a possible carrier.

Urine Specimens for Typhoid and Paratyphoid Organisms—Fifty favored continuation of the examination of urine specimens for typhoid and paratyphoid organisms; 15 were in favor of discontinuing this examination. It was pointed out that the objections to feces examinations apply equally to urine examinations, and in addition a number of individuals felt the examination of urine for typhoid organisms was unnecessary because urinary carriers are so infrequent and so seldom cause outbreaks.

Widal Tests for Typhoid and Paratyphoid Agglutinins—Thirty-two favored continuation of Widal tests for typhoid and paratyphoid agglutinins; 29 favored discontinuation of this test as irrelevant. Many held the opinion, borne out by our previous study, that the Widal test is of little aid in selecting possible carriers. The widespread use of typhoid bacterins in recent years has tended to minimize the importance of a positive Widal in the individual who is not ill. Many observers, including Gay,⁶ Rosenau,⁷ and Park, Williams, and Krumwiede,⁸ have stated that a positive Widal is found in from 50 to 75 per cent of carriers. None of the

carriers found in our previous study gave a positive Widal, and numerous individuals, with and without history of antityphoid inoculation, were positive and failed to give positive cultures even after repeated stool examinations. Since our previous study the Widal test has been discontinued as a compulsory requirement. However, studies on the type of agglutinins present (H and O) in an individual's serum are of much greater import than the ordinary Widal reaction as usually applied. Wyllie^{9, 10} has recently made pertinent observations on the relative occurrence of both the large-flaking, flagellar (H) and the small-flaking, somatic (O) agglutinins in a series of cases including normal individuals, carriers, inoculated individuals, and enteric fever patients. In general he points out the importance of the small-flaking reaction as presumptive evidence of the carrier condition as compared with the large-flaking reaction in normal inoculated individuals; also that the small-flaking agglutinins may be present shortly after prophylactic inoculation, but the titer falls to very low limits within a short time although that of large-flaking agglutinins may persist for longer periods.

Examinations for Endameba Histolytica—A few individuals expressed their opinion that examinations of stool specimens should be made for vegetative forms and cysts of *Endameba histolytica*. Cases of infection by this parasite are characterized by the fact that they occur sporadically or epidemically and never assume epidemic status¹¹ unless the recent outbreak emanating from Chicago can be considered in this light. Therefore, aside from the difficulty of obtaining specimens under practical conditions, such routine examinations would find little justification from an administrative viewpoint.

Examinations for Dysentery and Food Poisoning Organisms—Thirty-six

believed special effort should be made to detect dysentery and food poisoning organisms when examining specimens of feces and urine from milk handlers; 32 were of the opposite opinion. Our experience has been that it takes very little additional effort to examine specimens for significant members of the *Shigella* and *Salmonella* groups when culturing for typhoid and paratyphoid organisms.

Throat Cultures for Beta Hemolytic Streptococci—The examination of cultures for beta hemolytic streptococci in the throats of milk handlers has provoked the most discussion in regard to its significance. Twenty-eight individuals favored continuation of this test; 31 favored discontinuation. Many pointed out that streptococcus infections are often so transient that laboratory examinations may miss some infected handlers. Increasing the frequency of examination up to a reasonable maximum and making the employer responsible for reporting promptly to the examining physician any unusual throat condition in any handler will to some extent overcome this difficulty.

Nose Cultures for Beta Hemolytic Streptococci—Twenty-four favored continuation of making cultures for beta hemolytic streptococci on specimens of nose swabbings; 31 favored discontinuation of this examination. Some felt the making of a nose culture in addition to a throat culture on each individual was an unnecessary duplication of effort.

SIGNIFICANCE OF BETA HEMOLYTIC STREPTOCOCCI IN ROUTINE CULTURES FROM MILK HANDLERS

Discussion of the Methods Used—Swabbings from the throat and nose are received usually 18 hours after taking the specimens (maximum 24 hours). These are smeared over the surface of sheep blood agar in a Petri plate. The plates are incubated overnight (16 to 24 hours) and then examined for

colonies or areas showing typical beta hemolysis. When such colonies or areas are observed, slides are made and examined for the presence of streptococci. Ordinarily, no long chains are observed but a trained observer can easily and consistently eliminate those colonies showing hemolysis due to staphylococci and certain rod-shaped organisms. Colonies showing greening or methemoglobin production are not readily confused with beta hemolytic streptococci, although the alpha prime types of Brown¹² are occasionally difficult to classify. All colonies showing hazy or incomplete hemolysis are considered negative.

The method is designed for practical use in a laboratory doing a large variety of work with a limited personnel. Under these circumstances it has seemed the most expedient method available for complying with the requirements of the Milk Regulation Board that the examining physician determine by laboratory tests "that a milk handler does not harbor the germs of streptococcus sore throat." The method is by no means exact, and may be considered analogous to the presumptive test for the presence of coli-aerogenes organisms in water. It has been suggested that the method would be of greater value if enrichment cultures were made before plating. Beta hemolytic streptococci in the throat or nose of a milk handler are probably a menace to the health of consumers only when present in readily detectable numbers, so we consider enrichment methods an unnecessary refinement for this practical application.

Many persons have suggested that the use of pour plates or a combination of pour and streak plates would give much greater satisfaction than the method now in use. Others have suggested that incubation of plates under anaerobic conditions would be more satisfactory. The answer to these two questions probably awaits elucidation of

the oxidation-reduction capacities of the cultures during growth. Hagan¹³ has shown that viridans cultures under anaerobic conditions may be confused with beta types due, presumably, to scanty production of peroxide. Some stated they thought the time elapsing between the taking of specimens and streaking on plates was too long to permit satisfactory results, but the well known resistance of streptococci to drying (Kurth,¹⁴ Pasquale¹⁵) should make these forms more likely to survive than many other throat organisms. Several prominent authorities on streptococci have stated in personal communications that they did not feel this elapsed time was of practical significance in their experience.

Significance of Findings—The percentage of normal throats showing hemolytic streptococci of the beta type has been stated to be quite high by various workers.^{16, 17, 18, 19} Our experience with milk handlers has been that we have found approximately 1 per cent of all cultures examined positive. At first glance these two facts seem to be irreconcilable, but it must be considered that most of the work to determine the frequency of occurrence of hemolytic streptococci in normal throats has been very exhaustive and has included a study of tonsillar crypts, whereas our results have been obtained from surface swabbings. It is now generally understood that beta hemolytic streptococci are present in the tonsillar crypts of the great majority of people living in closely populated areas. It has also been shown by many investigators that beta hemolytic streptococci occur less frequently in persons from whom tonsils and adenoids have been removed. Williams²⁰ states:

In regard to the question of danger from healthy carriers of streptococci we must conclude that, since these organisms are so universally present, and since we know so little about their natural mode of increase in virulence, they must all be considered as po-

tential pathogens and, consequently, we all must be considered as potential carriers of dangerous streptococci.

Considering all these facts, it is logical to assume that cultures of swabbings from the surface of the throat tend to detect only those individuals who are harboring large numbers of beta hemolytic streptococci. In the absence of a better criterion, it has been the policy of this department to consider these individuals as potential spreaders of milk-borne disease and to insist that they be kept from handling milk until 2 successive negative cultures have been obtained at least 24 hours apart. The invasion of the surface membranes of the throat or nose from tonsillar crypts by these organisms may possibly be the first indication of the "increase in virulence" referred to by Williams.

The net result of our procedure is, then, to give the consuming public the benefit of the doubt from an epidemiological viewpoint by excluding from the handling of milk persons harboring large numbers of beta hemolytic streptococci. It has seemed advisable to regard these handlers as possible foci of milk-borne streptococcus infections since no satisfactory test is available for determining the virulence of streptococci.

Opinions of Examining Physicians—In addition to the questionnaire, opinions in regard to this particular examination were obtained from the physicians engaged to examine employees who handle milk. Only 3 stated definitely that they did not favor the present policy, that of removing a milk handler from handling milk upon finding beta hemolytic streptococci in the throat or nose until 2 negative cultures, 24 hours apart, had been obtained; while 105 favored the present policy, although approximately one-third of these favored it only as applied to handlers of raw milk. In their experience positive results have been obtained in the absence of clinical symptoms and negative re-

sults in the presence of throat symptoms which may or may not have been caused by beta hemolytic streptococci. The great majority stated these occurrences were only occasional in their experience, and some added that positive findings were often associated with signs of throat irritation or unusual redness of the handler's throat. More than one-half the physicians answered that these examinations had been of definite value to them. Another point mentioned by a few was that educational measures alone fall far short of their goal in gaining the coöperation of employees. A number felt more should be done to determine the virulence of the organisms found.

Measures Available for Determining the Virulence of the Organisms Found—

The criteria upon which we must ultimately base an interpretation of our positive findings must take into consideration the invasive power of the organisms isolated rather than their ability to produce a soluble exotoxin similar to or identical with scarlatinal toxin. Some idea as to the possible significance of a given strain may be obtained from morphological and biochemical studies, especially along the lines of the recent work of Edwards.²¹ Pathogenicity experiments on animals are of relatively little value in determining the invasive power of the organisms for humans. A correlation between the virulence of strains isolated from healthy carriers and their type specific substances as determined by Lancefield's²² technic might possibly be of value. Recently Tillett and Garner²³ have found that strains of beta hemolytic streptococci isolated from scarlet fever, septicemia, erysipelas, tonsillitis, acute nephritis, and otitis media secrete a soluble enzyme or toxin which has the power to lyse human fibrin, but not rabbit fibrin. Strains of the streptococci of non-human origin were completely non-fibrinolytic with few exceptions. If

this reaction is found to be at all specific there is some possibility of its being used as an index of the invasive power of any given strain of streptococcus for human beings. Some correlation has been shown between the virulence of beta hemolytic streptococci and ability to grow in defibrinated human blood by Todd.^{24 25, 26} McLeod²⁷ has, in addition to this, studied hemolysin production in fresh human serum as related to virulence and has briefly reviewed²⁸ the literature correlating other characteristics of these organisms with virulence.

In the light of practical experience we cannot concur in the view that the characteristics ascribed to "*Streptococcus epidemicus*" or "*Streptococcus scarlatinae*" are sufficiently broad to include the only streptococci capable of causing milk-borne septic sore throat or scarlet fever. It is pertinent to quote Andrewes²⁹:

It would seem that we have here a genus eminently successful in the struggle for existence, actively varying and constituting a group of "species in the making" which it is best consciously to approach as such. . . . The most abundant may be regarded as "centers of variation" around which the intermediate forms are grouped, and these centers may be treated as nascent species to which we may conveniently give names.

THE RÔLE OF THE LABORATORY IN A RATIONAL MILK HANDLER PROGRAM

We have discussed various viewpoints of the applicability of routine laboratory examinations of milk handler specimens to the general problem of preventing milk-borne disease. Although our own viewpoint has been greatly influenced by our experience in Connecticut we have attempted to evaluate impartially the opinions gathered from a questionnaire. In this evaluation certain fundamental principles have stood out from others and deserve incorporation in a program designed to include minimum requirements for this work.

A program designed to attain an acceptable efficiency in preventing contamination of milk supplies by milk handlers who are carriers of organisms capable of causing disease in the consuming group, must first of all include handlers of all milk supplies over which administrative supervision can be exercised with a thoroughness compatible with success. Control of the very small dairy supplying one or a very few families is extremely difficult, if not impossible. In regard to pasteurized supplies, assuming that every portion of the milk is actually pasteurized according to a satisfactory definition, with adequate inspectional and plant control facilities, it is necessary to subject to the program only those handlers who may contaminate the pasteurized product, directly or indirectly, in the processes of cooling, bottling, capping, or distributing the milk. In Connecticut nearly every employee in a pasteurizing plant is called upon to do work of this type at some time.

This program must then take into consideration the epidemiological significance of milk in the prevalence of the diseases from which the consuming public should be protected, and the means by which the incidence of milk-borne disease can be most effectively reduced with the funds available. Not only a laboratory program, but also administrative, educational, medical, and sanitation programs must be carefully considered to determine the proper place of each in the general scheme. The importance of milk as a foodstuff, its prominent place in the diet of all age groups, its peculiar physical and chemical properties which render it readily susceptible to contamination and capable of sustaining dangerous bacterial life, and the fact that all methods of production involve a certain risk of contamination from human sources, necessitate the utmost in careful planning from health officials to mini-

mize the hazard. The point is not that so much has been accomplished but that more can be accomplished to benefit the public health. The primary aim should be to attain more than merely acceptable efficiency in this field.

The relative importance of the various types of milk-borne diseases traceable directly or indirectly to carriers or cases among milk handlers can be judged from the number of consumers affected by each type since 1910. Infections with beta hemolytic streptococci occupy the front rank. Furthermore, the death rate per outbreak has been higher for these infections than for the others under consideration. The weight of these epidemiological facts is sufficient to make remedial measures mandatory in regions where these infections are common. Brooks³⁰ has advanced the opinion that many outbreaks of this type are "missed." Typhoid fever and related infections comprise the next most important group in which the human carrier has been implicated. Milk-borne diphtheria is comparatively rare and the use of toxin-antitoxin or toxoid will immunize the great majority of the susceptibles in any community and confine the occurrence of diphtheria from all sources to a few sporadic cases. Milk-borne tuberculosis is almost exclusively confined to the bovine type which is outside our discussion.

With these facts in mind, it seems rational to stress the importance of research to develop reliable methods of correlating the characteristics of the beta hemolytic streptococci isolated from throat and nose cultures with those of known pathogenic strains. Coincident with the development of satisfactory methods for this, it would then appear feasible to remove milk handlers from contact with milk when they harbor proportionately large numbers of organisms identical with pathogenic strains, and to keep them isolated until the carrier condition was cleared

up as determined by appropriate release cultures. This is particularly important on a raw milk supply if the handler is a milker, since he may infect the cows' udders and thus grossly contaminate the supply.

A well rounded program should include laboratory examinations to detect carriers of the typhoid-paratyphoid-dysentery group of organisms. Perhaps these may best be concentrated over a short time before or during the period when the handler first begins employment. An adequately large series of feces specimens should be examined to permit detection of the intermittent carrier. At least 2 urine specimens should also be included to detect urinary carriers. Primary attention should be paid to the organisms of typhoid and paratyphoid fevers, but the procedure can be adapted readily and with little additional effort to detect other significant organisms of the enteric group which are recognized causes of dysentery and food poisoning. Care should be exercised to insure the authenticity of these specimens. We have found little value in the Widal test as an aid in this connection and do not recommend its use. Even when specific attention is paid to the type of agglutination known as granular, small-flaking or somatic, negative results cannot be depended upon to exempt those who are not carriers from having stool specimens examined.

The detection of diphtheria carriers is probably of major importance only in areas where the disease is prevalent. In those areas a small number each of throat and nose cultures, taken at least 24 hours apart, for virulent diphtheria organisms may be included at the time the examinations of feces and urine specimens are made. These are recommended for the primary purpose of detecting those who are persistent carriers of these organisms. All positive findings should be confirmed by the use of a satisfactory virulence test.

The examination of sputum for *Mycobacterium tuberculosis* is relatively unimportant from the standpoint of milk-borne disease and may well be left to the discretion of the examining physician.

We see no sound reason for incorporating examinations for vegetative or encysted forms of *Endameba histolytica* in the program, in the light of our present knowledge, unless there is definite reason to believe milk an important factor in disseminating amebic infection in any given locality.

Local sanitary codes, rules or regulations should be amended to apply to handlers who are kept from handling milk under this program, and compatible release requirements incorporated.

Finally, a satisfactory physical examination made periodically by a licensed physician should be compulsory for all milk handlers subject to the requirements of the program. All specimens for laboratory examinations should be collected by him or under his supervision and all laboratory reports made only to him and to the proper administrative authorities. Both employers and employees should be made responsible for reporting to him, following his instructions, any suspicious clinical symptoms among the milk handlers. The examining physician should be required to inquire into each handler's history of past infection at the first examination, and the submission of specimens for laboratory examination over and above the minimum required should be left to his discretion.

SUMMARY AND CONCLUSIONS

1. Based upon statistics for the entire United States from 1880 to 1933 and for Connecticut from 1918 to 1933, the epidemiological importance of milk-borne diseases traced to human carriers and cases is discussed. Streptococcus infections have been responsible for almost 4 times as many cases as have the enteric infections, although the number of cases of the latter is of real sig-

nificance. Diphtheria has been relatively unimportant as a milk-borne disease from a national viewpoint, and no cases have been traced to milk in Connecticut during the period for which statistics are available. The large percentage of insusceptibles in the general population of many sections of the country tends to make the occurrence of milk-borne diphtheria sporadic in nature although there is still danger particularly for unimmunized children. The statistics indicate the necessity for remedial measures to control milk-borne infections.

2. Periodic physical examinations of milk handlers supplemented by certain routine laboratory tests are desirable for raw milk handlers and employees in pasteurization plants.

3. A revised estimate of the cost of the laboratory program in Connecticut is based on actual costs in 1933. The total cost for 24,487 laboratory examinations was \$7,966, making the average cost per examination about 32½ cents.

4. Authoritative opinions on routine laboratory examinations of milk handler specimens and pertinent comments on the Connecticut program are recorded and discussed in the light of experience in Connecticut.

5. The laboratory examinations discussed are: Throat and nose cultures for virulent diphtheria organisms and for beta hemolytic streptococci; sputum for *Mycobacterium tuberculosis*; feces and urine for typhoid, paratyphoid, dysentery, and food poisoning bacteria; Widal tests; feces for vegetative or encysted forms of *Endameba histolytica*.

6. Because of the relative importance of streptococcus infections, particular stress is laid upon a discussion of the significance of beta hemolytic streptococci in cultures from surface swabbings of throat and nose membranes of milk handlers. This culturing procedure tends to detect those individuals harboring large numbers of these organisms. In the absence of a reliable criterion for the virulence of these organisms, the consuming public is given the benefit of the doubt when the handling of milk by individuals found positive for typical beta hemolytic streptococci is prevented.

7. The rôle of the laboratory in a well rounded milk handler control program is discussed and the following program is suggested as reasonably complete when supplemented by educational measures:

a. A series of feces examinations for organisms of the enteric disease group should be made before or at the beginning of employment. This series should be large enough

so that chances of missing the intermittent carriers are slight.

b. A minimal number of urine examinations for the same purpose should be made to detect the relatively infrequent urinary carriers.

c. In areas where diphtheria is prevalent a minimum number each of throat and nose cultures for virulent diphtheria organisms, taken at least 24 hours apart, should be examined before or at the beginning of employment to detect persistent carriers of these organisms.

d. Examinations of throat and nose cultures for beta hemolytic streptococci should be incorporated as soon as reliable and practicable methods for determining the virulence or invasive power of any given strain are developed. In the absence of a satisfactory criterion it may be desirable in some areas to regard any milk handler as dangerous when he is harboring large numbers of typical beta hemolytic streptococci.

e. Satisfactory release requirements, compatible with local sanitary codes, rules or regulations must be provided for those milk handlers who are found harboring the organisms of, or suffering from, infectious diseases.

f. A thorough physical examination by a licensed physician should be given each milk handler before beginning employment and should be required of all milk handlers if maximum protection is to be afforded the consumer.

g. A careful inquiry into the history of past infection should be made at each individual's first examination.

h. All employees and employers should be made responsible for promptly reporting suspicious clinical symptoms of any sort in any milk handler to the examining physician, and the examining physician to the proper administrative authorities.

i. All required laboratory specimens should be taken by or under the supervision of the examining physician to assure authenticity of specimens, and additional specimens should be collected at his discretion from his findings.

j. All laboratory reports should be made only to the examining physician and the proper administrative authorities.

Recent Studies on Psittacosis*

K. F. MEYER, PH.D., B. EDDIE, AND I. M. STEVENS, F.A.P.H.A.

*George Williams Hooper Foundation, University of California, and
California State Department of Public Health,
San Francisco, Calif.*

PSITTACOSIS as a problem attracted the attention of the public health authorities during the pandemic of 1929-1930.¹ Single or group infections followed the exposure to parrots. At first, it appeared that the shipments of these birds from Argentina, South and Central America, with their ensuing distribution in pet shops and the contact infections in these places, would explain the pandemic. It is now evident that South America was not the only source of infection. Although the influence of the Argentine epidemic, with its subsequent rapid disposal of infected birds from the stores in South America, on the total number of human cases is great, it is quite obvious that other unknown factors must have operated, and other primary foci must have existed.

Under the influence of the universal and effective publicity which was given in the lay and scientific press, undoubtedly sporadic cases, which would ordinarily have escaped recognition, were brought to light. The data of the past 2 years amply support this statement. Following a case of psittacosis in a prominent person, attention is called to this supposedly rare disease. Several cases and even epidemics have thus, in

rapid succession, been discovered by health departments.

Even under California conditions where the interest has been kept alive among physicians and health officers, the report of one case is usually followed by the recognition of others. It is, therefore, the belief of those who have dealt with this malady that, during inter-epidemic periods, many cases have escaped detection and notification.

That birds other than South American parrots were involved in the epidemic of 1929-1930 in the United States is now fully realized. In December, 1929, Dr. Dannenbaum diagnosed a case of psittacosis (clinical and X-ray findings typical) in a patient who had received several shell parakeets from a San Francisco pet shop. In January, 1930, Sandoer and Coburis² saw a mild and a severe psittacosis infection in a mother and daughter who had handled "love birds" (shell parakeets) originally shipped from Los Angeles. Dr. Chisholm at Vancouver and Dr. Ridewood at Victoria, B. C., made similar observations in March, 1930 (McIntosh³).

Late in December, 1931, the Division of Epidemiology of the California State Department of Public Health was notified of the death of 3 people and the illness of a fourth, all of whom had been together shortly before their illness at a home in Grass Valley. The clinical

* Read before the Epidemiology Section of the American Public Health Association at the Sixty-third Annual Meeting in Pasadena, Calif., September 6, 1934, as an introduction to the demonstration of a teaching film: "A Disease of Parakeets Transmissible to Man" (16 mm., 1050 feet).

history of a typhoid-pneumonia-like disease, in form of a house epidemic, suggested the diagnosis of parrot fever. Inquiries established the fact that a healthy shell parakeet was in the home but that the mate had died on or about December 1, and that the husband, who was seriously ill, had buried it. A clinical examination of the patient in the light of these facts left no doubt that the symptoms were those of severe psittacosis. Subsequently, the presence of the virus in the sputum, and at autopsy in the lung, liver, and spleen conclusively proved the correctness of the diagnosis. Furthermore, the parakeet, which had been found in the house and held under observation for 43 days after the death of its mate, revealed on autopsy an enlarged spleen from which the psittacosis virus was readily obtained by mouse passage.

Incident to the publicity which was given to the dramatic deaths through contact with shell parakeets, reports of clinically typical cases of parrot fever, observed by physicians during the past few months, gradually filtered in from the southern part of the state. The victims had been exposed to parakeets of their own breeding or to birds which had been raised in the aviaries of Southern California.

Investigations conducted by the health authorities during the month of January, 1932, disclosed a vast bird breeding industry in parakeets and other birds, concerning which very little had been known. Laboratory examinations of sample birds obtained from some of these aviaries showed that a fairly large percentage of the shell parakeets carried the psittacosis virus in their spleens and livers. There was no doubt that psittacosis, as an infectious disease of the shell parakeets, existed in the California aviaries. Drastic measures of control could not be instituted since thousands of people, directly or indirectly, derived their liv-

ing from the breeding and raising of these birds. Aside from the public health aspect, the control of psittacosis assumed the importance of an industrial problem. It is this phase of the subject which had to be considered continuously in the investigations which were undertaken.

These data, together with previous and subsequent reports, rather forcibly call attention to the importance of the shell parakeet as a source and spreader of the psittacosis virus. One recalls the epidemic observed by Friedrich (1892) at Dühringsdorf near Landsberg, the house epidemic at Krefeld (1899),⁴ and at Zülrich (1909),⁵ the peculiar malady on the campus of the Veterinary College at the University of Zürich in January, 1930,⁶ and the isolated cases at Geneva (1929),⁷ Graz (1929),⁸ at Vancouver (1930),³ in England (1930),⁹ and in New York (parakeets of Cuban,¹⁰ Japanese and Dutch origin). More recently Fortner and Pfaffenberg¹¹ discussed their investigations undertaken in connection with 29 psittacosis family epidemics of 62 cases (54 in Berlin) and a mortality of 12 or 19.5 per cent. Equally significant are the reports from Saxony from 1931 to 1934.¹¹ Sixty-six cases of psittacosis with 15, or 22.7 per cent, deaths were caused by locally bred and raised parakeets.

It is apparent that the breeding establishments of many countries, dealing principally with the much desired shell parakeets (*Melopsittacus undulatus*), are infected with psittacosis and are a definite menace to the owners, the dealers of pets, and the patrons of these distributing agencies. Until it was recognized that domestic birds carry psittacosis the control of the disease, by preventing the traffic in tropical birds, appeared relatively simple. In view of the newer knowledge, the procedures have to be changed and the evil must be attacked at its root. The California studies furnish data which may serve as

guides in the formulation of adequate protective measures.

THE CAUSE OF PSITTACOSIS

The investigations conducted during the pandemic of 1929-1930 established as the etiologic agent of psittacosis a corpuscular virus, in part, filterable. In particular, the discovery of the minute, Gram-negative ovoid or spherical bodies in virulent human and bird tissues by Levinthal, Cole, and Lillie,¹² and the recognition of the white mouse as a very susceptible test animal for the virus by Krumwiede, McGrath, and Oldenbusch¹³ have greatly facilitated the practical diagnosis of psittacosis. The intraperitoneal injection of mice with the suspected material constitutes the best and safest procedure to demonstrate the presence of the virus.

No examination can be considered complete without a careful search for the elementary bodies described first by Levinthal, which possess in the diagnosis of psittacosis the same value as the Negri bodies in rabies. The particle size of the elementary bodies and their intracellular location (Bedson¹² and personal observations) render filtration of the virulent specimens an irregular procedure. Consequently, infectious sputa or other secretions or excreta cannot be safely freed from their bacterial contaminations by passage through infusorial or asbestos filters without the risk of losing the virus in part or in toto. Fractional centrifugalization of broth suspensions and repeated subcutaneous injections must be employed in the search for the psittacosis virus in contaminated specimens. The virus resists the action of glycerine (pH 7.4) for at least 66 days when held at 5° C. Desiccated bird spleens remain virulent at 5° C. for 277 days. Virulent contents of the cloaca rapidly lose their infectiousness on desiccation at room temperature.

The *Salmonella psittacosis* has been isolated in one instance only in the parrakeets of one local breeding establishment. In a shipment of 132 South American paroquets and parrotlets, 12 per cent of the birds harbored *S. psittacosis*, an organism closely related to "*S. aertrycke*" in the intestines, liver and spleen.¹⁴ Certain strains of the psittacosis virus increase in virulence for mice by passage and may infect in a dilution of 10⁻¹². Sputum strains and those from "epidemic" birds are more rapidly "passed" than the Australian parrakeet and the South American carrier strains.

SUSCEPTIBILITY OF BIRDS AND MAMMALS

A phylogenetic study of the natural hosts of psittacosis is still in progress. From a practical standpoint it is important to recognize that a great many species of birds, various rodents, monkeys, etc., may be infected by injection or by feeding. By exposure to infected parrakeets, the susceptibility of the fowl (*Gallus gallus* belonging to the order *Galliformes*), parrotlet, conure and cockateel (order *Psittaciformes*), Java sparrow (order *Passeriformes*, family *Ploceidae*), canary, nonpareil, Bengalese (family *Fringillidae*), and Pekin robin (family *Timaliidae*) has been definitely established by placing them in the breeding pens of the budgerigars. Particularly susceptible are the Java sparrows. These birds may serve as excellent sentinels for the detection of the presence and the dissemination of the virus in a room or pen in which parrakeets with latent psittacosis are held. Young chickens intimately exposed may succumb to psittacosis. The virus grows freely in the chick embryo when placed on the chorion-allantoic membrane of the developing egg.

EPIDEMIOLOGY OF HUMAN PSITTACOSIS

Since December, 1929, 189 cases of psittacosis and 14 suspects with 40

deaths, or 21.28 per cent mortality, have been reported in the United States and Canada. One hundred and seventy cases (14 suspects) had direct or indirect contact with diseased shell parakeets. In California, 70 cases resulted from exposure to locally raised birds, while in other parts of the Union or in Canada shipments of the California birds were responsible for 98 additional cases. During the same period 17 infections due to contact with parakeets from Cuba, "the Orient," Yokohama, and Holland have been recorded. The origin of the parakeets in 2 cases (Wisconsin and Minnesota) remained undetermined. Two patients contracted their infections in California through exposure to canaries.¹⁵ The virus was demonstrated in the spleen of 3 of 12 canaries. In the California series, at least 3 and in all probability 6 cases were human to human transmissions.

In the Pittsburgh outbreak, a non-fatal case transmitted a fatal infection to the nursing sister. For the first time, the transmission chain was conclusively proved in 2 instances. The psittacosis virus was demonstrated in the sputum of the patient and in the blood and sputa, respectively, of the 2 nurses who became infected. In another instance, the lung of the fatal case was virulent and the sputum of the nurse contained the same infective agent. The clinical manifestations repeated themselves with their usual variability in intensity; in this respect they differed in no way from the classical descriptions available.

The incubation time, although in many instances difficult to establish, is definitely known in 15 cases and varied from 7 to 14 days after initial contact. In 3 cases a single exposure occurred and the incubation time was 7, 8, and 9 days, respectively. In human to human transmission the interval between the onset of the illness and the discharge of the nurse from the case was 8 and 13 days. Important is the observation

that 30 days elapsed between the death of a woman and the first symptoms of psittacosis in her nurse. This must be considered an exceptionally long incubation period since it is reasonable to suspect that the transfer of the virus occurred a few days before the death.

No explanation can be offered for the noteworthy fact that the same degree of contact and the same virus may induce diseases of varying degrees of severity. It is not unlikely that the susceptibility of man is quite variable and that a fair percentage may pass readily through the disease which remains in a latent or sub-clinical stage. In isolated cases, exposure to sick or dead shell parakeets may induce clinical manifestations which, in any one patient or in any stage of the malady, are insufficiently characteristic to enable the physician to make a diagnosis. The recommendation, therefore, may be safely made that, until the sale of non-infected birds can be guaranteed, it is well to be biased and to suspect psittacosis whenever a patient has recently brought birds liable to this disease into his or her household and suffers from severe influenza, complicated by a "migrating" pneumonia. However, it is imperative that this suspicion or a clinical diagnosis be confirmed even though present laboratory methods frequently decide merely in retrospect. A definite laboratory diagnosis is desirable for epidemiologic reasons.

An examination of the blood for virus has little diagnostic value. In 28 clinical cases examined, the citrated blood of 3 patients infected mice when the blood was collected on the 1st, 2nd, and 4th day, but not on the 9th, 16th, or 17th day of the illness. On the other hand, the examination of sputa, first introduced by Rivers and Berry,¹⁶ has proved quite valuable. In a series of 60 sputa, the virus was conclusively demonstrated in 14 patients whose expectorations were collected on

the 5th, 6th, 7th, 9th, 10th, 12th, 14th, 16th, 23rd, and 37th day, respectively, after the onset. One patient furnished a positive sputum on the 5th and on the 10th day but a negative one on the 16th day, while in a fatal case, the secretion was infectious on the 14th, 19th, and 23rd day of the disease. The elimination of the virus is irregular, and repeated examinations of 24 hour specimens should be made. The autopsy material from 6 human cases was studied. The lungs invariably contained the infective agent in such concentrations that the mice succumbed in from 6 to 8 days with typical lesions. The pathologic and histologic lesions correspond to those described by Lillie.¹⁷

Further experiments and observations are needed before a definite opinion can be expressed concerning the pathways of transmission of the virus from birds to man. The apparent high infectivity of the dispersed psittacosis virus is shown in the histories in which very short exposures occurred in pet shops, households, and baggage cars where diseased birds were kept. There is considerable evidence that *aerial convection* plays a very important rôle. Monkeys are non-susceptible to subcutaneous administrations of virus while intratracheal injections may induce a disease resembling human psittacosis. The ordinary means of contagion cannot be excluded since the handling of dead birds, feathers, excreta, etc., is frequently reported.

An interesting characteristic of psittacosis outbreaks is the occurrence of multiple cases in the same household. The great epidemics of the past occurred during the winter months. Epidemiologists, therefore, have expressed the opinion that the prevailing disposition to respiratory infections during the colder months of the year favored the spread of psittacosis. Recent observations in California and the United States at large

have shown that the seasonal fluctuations of the disease are influenced by the prevalence of infected birds. Many cases have been seen in September and October, and severe psittacosis is not uncommon in midsummer. Usually, in the fall and early winter, immature carriers, sick birds and their mates, which cannot resist the rigors of transportation, reach their destination. The climatic factors are of significance only in so far as they affect the resistance of the birds and the frequency with which human beings may be brought in contact with them through prolonged exposure in the closed rooms of a winter household.

The majority of psittacosis infections have occurred in people of middle age. The lower susceptibility of children is well known. Intimate exposure of children to the same parrakeets which infected parents or older relatives indirectly, has repeatedly been noted. Careful investigations indicate that these contacts failed to produce disease in children. The greater frequency of psittacosis in women (California 48 ♀ : 22 ♂) is, in part, due to the fact that they are either engaged in the breeding of parrakeets for their livelihood, or as lovers of pets they come more closely in contact with birds. That persons engaged in the breeding, raising, transportation and sale of birds are particularly liable to psittacosis is fully recognized. Of the 70 cases of psittacosis infection reported in California, 27 or 38.5 per cent were in owners of large or small parrakeet aviaries or in members of their families. Three other groups—nurses, physicians, and laboratory workers—are equally exposed to the risk of occupational psittacosis.

The case mortality rate in the 187 cases was 40, or 21.28 per cent, or for the California cases of the period 1929 to 1934, 70 with 14, or 20 per cent, deaths. No fatality occurred below age 38. Very much higher rates have been

reported in the past. In one house epidemic in California, the rate was 100 per cent. It appears reasonable that the systematic inquiries which followed the discovery of 1 fatal case usually revealed 1 or 2 others but milder cases, and thus helped to ameliorate the staggering mortality.

THE EPIDEMIOLOGY OF AVIAN PSITTACOSIS

Although the histories of the California single or group infections of psittacosis mention exposure to sick or dead shell parrakeets, it has unfortunately been possible in but 4 instances to secure the virus for examination from these sources. At the time the cases had been clinically recognized, the carcasses had been buried or destroyed and only the mates of the pairs of budgerigars, which brought the disease into the household, or parrakeets from the same breeding establishment which furnished the epidemic birds, were available for examinations. Thus in 3 instances, apparently healthy shell parrakeets were submitted for study. According to the epidemiologic inquiries, 40 or at least two-thirds of the owners of birds had been exposed to sick or dead parrakeets, while 19 had merely had contact with "healthy" birds. Previous observations left no doubt that apparently healthy parrakeets may transmit a disease to man, but since the fatalities among parrakeets in aviaries are by no means uncommon despite emphatic denials by the bird raisers, it cannot be denied that probably a far larger number of human psittacosis cases resulted from exposure to sick and dead birds. However, it must be kept in mind that Fortner found 30 of the 35 parrakeets involved in the German outbreaks to be clinically normal.

It has been demonstrated in a large series of tests that the acutely ill parrakeets or those suffering from re-

lapses are more liberal disseminators of the virus than those with latent infections, but clinically normal. Unfiltered suspensions of the spleen, liver, contents of cloaca and nasal mucosa, removed at autopsy with separate instruments, have been tested on white mice with the following results:

1. Epidemic birds: spleen and liver contain virus 4; cloaca content infectious 4; nose infectious 3.
2. *Acute* fatal infections not connected with outbreaks: spleen and liver contain virus 36; cloaca content infectious 25; nose infectious 26.
3. *Latent infections*: (64) spleen and liver contain virus 59; cloaca content infectious 21 (2 weak); nose infectious 30.

In the acute stage, both the nasal and fecal elimination of the virus may be demonstrated to occur simultaneously, although birds may be encountered in which either no virus discharge may be demonstrated or it may be found only in the nasal mucus or the cloacal contents. The latter are very rich in virus when the birds exhibit signs of diarrhea or polyuria. Since the kidneys are as a rule highly infectious, while the small intestines and colon are not, it is reasonable to assume that, in some of the birds at least, the urine may be the vehicle for the virus. Parrakeets with splenic or hepatic localization eliminate the psittacosis virus slightly more frequently by the nasal than by the anal route. In a small percentage of birds, the viscera were free from virus while the nasal mucosa was infectious; several presented anatomically the residuals of past infections. Breeding hens may carry the virus in the ovaries or in the yolk of the eggs found in the oviduct; congenital transmission of the psittacosis virus is thus suspected. As a whole, the studies lend support to the epidemiologic observations that a visibly diseased bird is more dangerous than carriers on account of the abundant contamination of the environment with highly infectious fecal material.

The epidemic birds or their mates submitted for examination were found to be immature, less than 6 months old. Experimental infections and numerous surveys have shown that the immature and sexually undeveloped parakeets succumb more readily to psittacosis than the mature breeding birds. For example, the mortality in a flock of 33 *immature* parakeets from infected and non-infected aviaries, injected with a passage of virus active in a dilution of 10^{-8} , was 10, or 33 per cent, while by comparison under identical experimental conditions, 72 *mature* birds from the same breeding establishments showed a mortality of 3, or 4.1 per cent. Equally corroborative are the data collected from the numerous surveys of aviaries. A sample of 100 birds from one aviary consisted of mature and immature parakeets. Anatomically and by mouse tests, 8 per cent of the mature and 48 per cent of the immature birds were found to harbor the virus of psittacosis. In 163 aviaries, the 699 parakeets anatomically suspected of psittacosis were classed according to age as follows: mature: 378 of 3,814, or 9.9 per cent; immature: 321 of 1,850, or 17.3 per cent.

Relatively little is as yet known concerning the flock infection and flock immunity. Mature and immature shell parakeets selected from pens in which latent psittacosis has been demonstrated may be experimentally infected. By comparison with birds from non-infected aviaries, the mortality is lower (infected 17.3 per cent; non-infected 35 per cent). Aside from the lower mortality, the rate of recovery is slightly greater. Within 28 to 36 days, 33 per cent, and within 135 days, 77 per cent of the parakeets from infected aviaries free their organs of the virus. Only 39 per cent of the birds from non-infected premises recover within 51 to 144 days. In flocks of old birds, one may find parakeets which dispose of the virus

inoculated within 4 to 5 days. Our present knowledge is entirely inadequate to explain this resistance; the preliminary studies merely indicate that it is not associated with neutralizing antibodies. Ample data are available to support the general observation that the latent infections in a flock of parakeets may, within 6 to 8 months, be reduced to 1 or 2 per cent. As a rule, a very weak virus may be demonstrated in the spleen and liver. The cloacal content and nasal mucus is, as a rule, free from virus. These carriers are non-infectious; ricebirds exposed in the same cage remain well. However, psittacosis is not eliminated from the aviary.

With the resumption of breeding operations after an elapse of from 6 to 8 months, psittacosis will flare up again and acute parrot fever in young and even old birds will be noted. A variable percentage up to 50 per cent of the 2 to 4 months old parakeets show at autopsy acute or chronic lesions of the disease. The virus is present in the spleen, liver, cloaca, and nose. When mingled with susceptible birds, they readily disseminate the infective agent. Any aviary once infected remains so, despite excellent sanitary management and systematic removal of sick birds. Complete isolation for 1 year may reduce the number of carriers as judged by the anatomical lesions and the demonstration of the virus by mouse tests, but it never eradicates the disease.

That isolation and quarantine, particularly the customary 2 or 4 weeks, offer little or no protection has been amply attested by the experiences of recent years. It will suffice to submit some observations to illustrate the prolonged intrinsic infectiousness of the avian psittacosis carriers and the relatively long incubation time.¹⁸

1. A pair of apparently healthy "parakeets," though suffering from latent psittacosis, infected ricebirds ex-

posed in the same cage on the 1st, 21st, and 40th, but not on the 87th day. The incubation time in the ricebirds was at first 8 to 10 days with death on the 14th and 15th day; later it was 40 days with death on the 48th day.

Of 2 ricebirds exposed to 2 shell parrakeets with latent psittacosis, 1 contracted the disease on the 50th day and was sacrificed in a moribund stage on the 55th day of exposure.

2. The longest time intervals between injection and death observed by Meyer and Eddie were 41, 61, and 98 days following the intramuscular application of the virus. In exposure tests, sickness observed on the 95th day was followed by death on the 106th day.

In order to detect acute avian psittacosis in a shipment of birds, it is obviously necessary to extend the quarantine from 2 to 3 weeks, preferably 5 months. Of course, it must be realized that even this precaution gives no assurance that latent psittacosis is non-existent in a foreign shipment, as observations on Australian¹⁰ and South American psittacine birds¹⁴ have clearly demonstrated. Finally, it is of some interest to know how psittacosis may have invaded the California aviaries. The original stock came from Japan and various other sources, even from Australia. It is now proved that the native Australian budgerigar is spontaneously infected, and thus it is reasonable to assume that avian psittacosis was introduced into the breeding establishments, and since it was not recognized, it spread, through no fault of anyone, to a large percentage of the aviaries. As long as only carefully selected mature birds were distributed, the closed latent infections presented no menace to man. Mass breeding by the inexperienced, distribution and mixing of immature birds from various aviaries, perhaps cyclical factors in the infectiousness of the virus, finally lead to the situation with which the public health

authorities and the industry are now confronted.

PROTECTIVE MEASURES

Theoretically, psittacosis is a disease which could be easily controlled, provided the public would appreciate the possible danger inherent in contact with birds, particularly those of unknown origin. This is obviously impossible when a group of people earn their living by raising parrakeets. Earnest attempts were, therefore, made to eliminate from the traffic those birds which are particularly dangerous spreaders of the disease. After 2 years of struggle to accomplish some degree of protection by means of restrictive measures, such as isolation for 30 days, it became apparent that without an extensive force of inspectors and an expensive system of continuous control the diseased birds cannot be eliminated from the usual local and national traffic.

As already emphasized, in California, psittacosis is not only a public health but also an industrial problem. Both interests are best served by the creation of an aviculture free from psittacosis. The speed with which this program may be executed depends entirely on the fund which may be available to make surveys and to eliminate the aviaries which harbor infected birds.

A recent survey of 164 aviaries by the Department of Public Health has shown that approximately 55 per cent of the establishments yielded by repeated examinations parrakeets which were anatomically, and by mouse tests, free from latent psittacosis. Furthermore, several aviaries, held under observation for nearly 2 years, have furnished non-infected immature birds every time they have been sampled. It is, therefore, reasonable to hope that in due time a nucleus of aviaries free from disease may be created. Plans are in progress to establish a number of so-called "rehabilitation aviaries" which

will furnish the breeding stock for the building up of the industry. These aviaries, managed and maintained by a group of bird breeders, remain under the supervision of the Department of Public Health laboratory in order to insure the permanent elimination of psittacosis in the breeding pens. Until the desired goal—no psittacosis in the American bird industry—has been reached, California will restrict the sale and distribution to lots of parakeets which have been sampled and tested in the laboratory. At the same time, every effort will be made to alleviate the hardship and suffering imposed upon the industry by the restrictive measures which of necessity had to be adopted in order to protect the public health.

Studies of Correlated Human and Bovine Brucellosis*

Statistical and Serological

R. V. STONE, F.A.P.H.A., AND EMIL BOGEN

*Director, Bureau of Laboratories, Los Angeles County Health Department, and
Pathologist, Olive View Sanatorium, Los Angeles, Calif.*

THE part played by the ingestion of raw milk from cattle infected with *Brucella abortus* in the pathogenesis of undulant fever is still minimized by many of the foremost workers in the field,¹ as well as by the practical dairymen,² who resent any additional aspersions on their product. The dramatic increase in the number of reported cases of this malady during the past few years in every state of the Union³ makes this a matter of more than academic interest. The present study may aid in the elucidation of some of the moot questions in this situation, and lead to a better evaluation of the factors concerned.

BOVINE INFECTION

Since goats' milk is consumed in this country only in exceptional cases, the caprine sources of infection cannot be expected to play here the important rôle which they have been shown by Bruce^{4, 4a} and others,⁵ to hold in reference to Mediterranean undulant fever. In several instances hogs have been shown to be the responsible agents,⁶ infection resulting from contact with the flesh of infected animals.⁷ How-

ever, neither porcine nor caprine contacts can be discovered in the histories of the vast majority of the cases of *Brucella* infection thus far reported in this country, and it is natural that suspicion should fall upon the cow as an important agent in the transmission of this disease.^{8, 8a}

The prevalence of infectious abortion due to the *Brucella abortus* in cattle has been attested by observers all over this country,⁹ as well as by many abroad.¹⁰ The studies of Meyer and his coworkers^{11, 12} have shown that California cattle have not escaped this disease. Not all herds, however, shows the same amount of infection. Examination of all the cattle in 3 herds supplying 3 institutions for the care of tuberculous patients in Los Angeles County showed that the incidence of infection varied from 6 to over 50 per cent, as revealed by agglutination titers of 1/50 or higher, with an average of nearly 30 per cent showing agglutination in titers of 1/100 or higher.

HUMAN AGGLUTINATION TESTS

An attempt was made to determine the incidence of infection with *Br. abortus* among the persons consuming the raw milk from these herds. During the first half of the year 1930, more than 1,200 specimens of blood were

* Read at a Joint Session of the California Association of Dairy and Milk Inspectors and the Laboratory Section of the American Public Health Association at the Sixty-third Annual Meeting in Pasadena, Calif., September 6, 1934.

TABLE I

AGGLUTINATION TESTS ON COWS

Institution	Total	Negative	Positive at		Per Cent Positive	
			1/50	1/100	1/50	1/100
A	132	32	22	47	52	35
B	32	24	0	2	6	6
C	31	15	5	4	28	12

taken from patients at these 3 institutions, and tested for agglutinins of *Br. abortus*, by the macroscopic method recommended by the University of California Committee.¹³ In institution A, consuming milk from the most heavily infected herd, 66 instances of positive agglutination were discovered, while the 2 institutions, B and C, receiving their supplies from the least contaminated cattle, did not present a single positive test. Moreover, none of the 176 persons examined upon admission to institution A before they had begun to consume the contaminated milk, showed the presence of agglutinins for these organisms.

TABLE II

AGGLUTINATION TESTS ON PATIENTS

	Total	Positive
A: Old Patients	842	65
Employees	12	1
New Admissions	176	0
B	56	0
C	98	0

CLINICAL SIGNIFICANCE

The above figures appeared to show conclusively that the occurrence of positive agglutination tests for *Br. abortus* in the blood of these persons was a direct consequence of the drinking of raw milk from the cattle which showed a high incidence of positive reactions. Since all of these results were secured in the course of a routine serological examination of all persons in the institution, and not in response to

any clinical indications, some doubt was entertained as to their clinical significance, and it was even suggested that this merely represented an immunization of the patients by the ingestion of dead or living organisms without the production of actual infection. It was admitted that perhaps there might have been symptoms in some of these cases which had been overlooked or attributed to other causes. This was indicated by the results of other studies carried on by the Bureau of Laboratories of Los Angeles County, for instance, where of 1,500 sera submitted for examination for syphilis, in which there was no indication of febrile disease, only 1 specimen was found to contain agglutinins for *Br. abortus* in dilutions of 1/100 or higher, while 83, or nearly 22 per cent of all the "typhoid-Widal negative" sera submitted for examination for the possibility of typhoid fever (378 in number) were found to contain such agglutinins in this or higher dilution.¹⁴ Since positive agglutination for these organisms appeared so much more frequently among the groups showing symptoms of febrile disease than among others, it appeared logical to look for a higher incidence of symptoms in those showing such positive agglutination tests. Accordingly, the individuals showing positive agglutination reactions were subjected to special scrutiny.

DURATION OF EXPOSURE

The 66 individuals possessing agglutinins for *Br. abortus* constitute 7.7 per cent of the 854 who were tested in

Sanatorium A. When we consider the duration of stay in the institution, we find that the incidence of the positive tests is much higher in those who have had a longer exposure—nearly 15 per cent in those who were at A for more than 2 years, and less than 2 per cent for those who entered during the current year. It is quite to be expected that the incidence of the infection is related to the duration of exposure, but it suggests that the apparent immunity of those not so infected is merely relative, or illusory, and that heavier or more sustained exposure might result in much higher incidence of the disease.

HEIGHT OF TITER

On the other hand, the patients having the longest exposure to the disease have relatively low titers of agglutinins in their blood, and the highest titers occur in those who had been in the institution for from $\frac{1}{2}$ to 1 year prior to the beginning of this study.

ings obtained by repeating the tests in the positive cases during a half-year or so. In general, the successive tests show a diminution of titer, especially in the patients who had been in the institution for a long time, while in the more recent patients the titer continued to increase.

SEX AND AGE

Although the population of the institution comprises somewhat more females than males, a few more males gave positive agglutination tests than females. This slight preponderance is in harmony with the figures generally reported by other investigators, but the explanation sometimes given, that the outdoor exposure of the males to contact with the living infected animals or their tissues in the slaughter houses is evidently not the solution here.

The age incidence here is at variance with that commonly found, the proportion of subjects under 10 being much

TABLE III

DURATION OF EXPOSURE TO RAW MILK AND TITER
MAXIMUM TITERS

Duration of Exposure	Total Cases	Total Per Cent		1/20	1/40	1/80	1/160	1/320	1/640	1/1,600
		Positives	Positive							
Over 2 years	91	13	14	2	3	3	3	2
Over 1 year	120	16	14	1	2	3	6	2	2	..
6 mos.—1 year	178	13	8	3	1	1	3	..	4	1
Employees	12	1	8	1
Under 6 mos.	250	19	7	1	6	3	6	3
During study	203	4	2	1	2	1
Total	854	66	..	8	12	10	21	8	6	1

Since it has been shown in laboratory experiments as well as field studies that the agglutinins to this organism may appear quite rapidly, or may increase over the course of many months, and that they tend gradually to disappear, our findings appear quite consistent with what might be predicted from these general considerations. This impression is borne out by an examination of the find-

greater than that previously reported. The incidence of the disease among the younger patients is more than twice that found among the older ones. The markedly greater consumption of milk by the younger patients (each child consumes a quart of milk daily in addition to the regular meals, while the adults have no such fixed ration, and are noted on the wards to consume much

less), together with the generally longer duration of hospital and sanatorium stay by the younger patients, thus increasing the total amount of exposure to the milk-borne infection, may serve to account for these differences. The lack of similar findings in the reports of other studies seems to be mainly due to the fact that insufficient numbers of children were tested.

STAGE OF TUBERCULOSIS

The stage of tuberculosis in these 66 persons was definitely earlier than that of the average of the patients, only half of them being far advanced pulmonary cases, while three-fourths of the patients have already reached that stage; more than one-fourth of the positive agglutination subjects were juvenile or hilar types, although they represented but one-eighth of the sanatorium patients. The titers in these groups bring out this phenomenon even more strongly, since the patients showing high titers of 1/320 or more, included less than one-fourth of far advanced cases. This is contrary to our initial supposition that patients with advanced disease, and especially with intestinal ulceration, should be more susceptible to infection, and suggests that the factors responsible for the invasion and agglutinin formation are not simple mechanical or infective lesions providing portals of entry for the organisms. Perhaps the relatively larger consumption of milk by the less severely affected patients may help to explain this phenomenon.

COURSE OF DISEASE

The course of the disease in the 66 persons showing evidence of complicating *Br. abortus* infection was significantly milder than has been the general experience of tuberculous patients in this institution. Of the 30 patients so far discharged, 27, or 90 per cent, have been recorded as arrested or im-

proved, and only 2 (or less than 7 per cent) died in the institution.

An autopsy was performed on 1 patient with a positive agglutination in dilutions of 1/100, and a history of irregular temperature rises, but far advanced pulmonary tuberculosis of fibroid type with death from hemorrhage was the only finding noted. The exacerbation of the tuberculous process that might be expected to accompany a complication characterized by an increased monocytosis, as suggested by the work of Sabin and her coworkers,¹⁵ and by Theobald Smith,¹⁶ was conspicuously absent in this series, and one is almost tempted to suggest a beneficial effect. However, the probable explanation is that the patients doing well so far as tuberculosis is concerned, consumed more milk, thereby exposing themselves to more massive and frequent infections than those in whom intestinal and laryngeal complications had made milk drinking less pleasant, with consequent difference in the incidence of the infection in the two groups.

TEMPERATURE CURVES

Since daily temperature records were available for all of these patients, it should not appear difficult to pick out those suggestive of undulant fever. However, in more than one-third, there was so much elevation of temperature that was obviously or apparently due to active tuberculous disease that it was impossible to consider any part of it separately as related to the abortus infection. Another third of the records failed to disclose any distinctive departure from a normal temperature curve. In but 18 instances were there evidences of fever that could not be explained by other evident causes. The majority of these were in children or other individuals presenting little evidence of tuberculous activity, and it is perhaps significant that two-thirds of them occurred in groups of patients

TABLE IV

TITER AND FEVER

manifesting the higher titers of agglutinins.

This suggests that the occasional febrile disturbances recorded bear a direct relationship to the abortus infection.

SKIN TESTS

Intradermal inoculation with a purified abortus protein¹⁷ for the detection of sensitization to this organism was performed in June, 1930, in 39 individuals, and in only 13 were the reactions greater than those elicited by a control inoculation of paratyphoid vaccine. The tests were repeated in August on 42 individuals with a whole abortus bacillus killed vaccine,¹⁸ and 14 positive reactions were obtained. Altogether of 45 individuals tested, less than half reacted positively to either of the antigens used, and in both the majority of the positive reactions were rather mild, and often questionable. In several instances with the use of the whole killed bacillus antigen, there were reactions with fever following the inoculation; 1 patient had a systemic reaction with severe chills, and in another there resulted a slough which persisted for several weeks.

Most of the positive skin tests were obtained on patients who showed a rather high agglutinin titer, and conversely, most of the patients with the higher agglutination values showed a positive skin test. No positive skin test was obtained on any of the 5 individuals with negative agglutination tests. In several individuals the positive skin test, especially when accompanied by

systemic reactions was followed by a rather marked eosinophilia, reaching 14 per cent in 1 case, but this was not a uniform finding. Hematological studies were otherwise disappointing, the monocytosis reported by Smith and the leukopenia by other workers were generally absent, or otherwise explainable.

CLINICAL MANIFESTATIONS

Consideration of the clinical manifestations in the 66 individuals who had positive agglutinins for *Br. abortus* led to a tentative diagnosis of undulant fever in 6 instances. All were females, 4 below the age of 15, and 2 in their 30's. Three were recorded as preventorium cases or juvenile type tuberculosis, 2 were minimal cases, and 1 far advanced phthisis. Five had been in the institution for more than 6 months, and 1 had entered just before the beginning of the study, but did not develop symptoms until over 4 months later. In each there was a history of an unexplained fever, usually recurrent or undulating in type, generally without severe accompanying symptoms, disappearing after some months. The reports show that all these were of the mild or ambulatory type, but nevertheless all had sufficient symptoms to command attention and produce some distress. Skin tests were positive in 4 and negative in 1, the other not having been tested. Agglutinins were present in a titer of 1/800, 1/640, 1/400, 1/200, 1/200, 1/50, respectively. In 2 they were absent on later tests, in 4 they were somewhat increased.

POSSIBLE UNDULANT FEVER

In fully a score of the remaining patients there was some evidence to justify the suspicion of undulant fever, but the cases were insufficiently clear-cut to establish a definite diagnosis. Just half were males, and half under the age of 20. Half of them were juvenile or preventorium or minimal cases, the other

10 were mostly far advanced. Ten of them had arrived during the preceding 6 months, or the first months of our investigation. All but 1, who had not recorded his temperature, had had fever during their sanatorium stay, but in the majority of the cases it was more continuous than in the more typically undulant fever types, in some being mixed with the elevation resulting from active tuberculous disease. In only 4 was there a strongly positive skin test; in 3 there was a slightly positive reaction, and in 10 the test was negative. The titers on agglutination were quite high, in 1 case 1/1600, and more than half of them were 1/100 or higher, only 1 being as low as 1/20, and in this case there was a partial agglutination as high as 1/200.

NO EVIDENCE OF UNDULANT FEVER

It was difficult, however, to elicit any evidence of clinical disturbance resulting from brucellosis in 40 individuals with positive agglutination tests. Of these, 25 were males, and 25 were over 20 years of age. Nearly half of them had been at the sanatorium for less than 6 months and most of them had far advanced pulmonary disease on admission. Nevertheless most of them were practically afebrile throughout their stay in the institution, and the 12 who did have fever could easily attribute it to their tuberculous lesions. The agglutinin titers in this group were generally low, only 2 being higher than 1/200 and the skin tests were negative in the majority of them.

SUMMARY OF CASES WITH POSITIVE AGGLUTINATION TESTS

In summarizing the clinical manifestations we may note that the patients manifesting symptoms showed a higher titer of agglutinins, were younger, and in an earlier state of tuberculosis, mostly female, and had been in the institution somewhat longer than those

who did not show such clinical indication. Taking the other aspect, we may note that of the patients with positive agglutination tests for undulant fever, those with the high titers showed more clinical evidence of brucellosis, as did also those who were younger and in an earlier stage of the disease but longer in the institution, that more of the women showed symptoms than did the men, and only half of those with positive skin tests showed other clinical evidence of the disease.

Additional support for the suggestion that undulant fever infection was more apt to occur in the healthier patients on account, perhaps, of their more generous consumption of milk is the fact that the symptoms that appeared to be due to this infection were present in only 1 of the far advanced patients, while in 5 of the juvenile or minimal types symptomatic evidence did exist. No evidence of such symptoms could be discovered in three-fourths of the far advanced cases; some such symptoms appeared in the majority of earlier ones.

It appears that of the 66 patients (constituting nearly 8 per cent of the entire number exposed to drinking the infected raw milk) who developed agglutinins against the *Br. abortus*, 6 cases showed sufficient clinical manifestations to warrant a tentative diagnosis of undulant fever, while more than 3 times this number had symptoms, otherwise unexplained, which may have been attributable to this cause. This is in accord with the summary of Alice Evans "Chronic Brucellosis."^{18a} In no instance, however, were the symptoms of the grave nature generally associated with Mediterranean or Malta fever, and no deaths could be reasonably attributed to this cause.

COMPARISON WITH INCIDENCE PREVIOUSLY REPORTED

It is interesting to review the incidence of agglutinin formation and clin-

ical undulant fever reported by other observers in connection with the consumption of raw milk from cattle suffering with infectious abortion. Unfortunately, the data for such comparison are fragmentary and often lacking in facts necessary for correlation, but it may be noted that in general surprisingly good agreement exists with our figures. Thus King,¹⁹ in New York, found that about 13 per cent of the patients who drank infected milk developed agglutinins to *Br. abortus*, while Hardy,²⁰ in Iowa, found a fraction under 10 per cent whose agglutinins were active in a titer of 1/20 or higher. In King's series, 12 per cent of the positive cases showed clinical evidences of undulant fever. Our corresponding figures of 11 per cent of exposed patients developing agglutinins, and 8 per cent developing agglutinins presenting clinical manifestations, is not far from the figures reached by other investigators.

RE-CHECK OF BRUCELLIASIS AGGLUTINATION TESTS—OCTOBER—DECEMBER

Six months after the completion of the first tests on all patients at Sanatorium A and the consequent testing and clearing out of the herd, all of the cattle reacting positively to agglutination tests for *Br. abortus*, sera were taken for repetition of the tests on all patients in the institution. More than 920 sera were tested from 850 individuals. The results are strikingly in accordance with the conclusions drawn from the earlier figures. Out of 500 patients and employees who had come to A since the milk had been freed from the infectious organisms—at first by pasteurization, and later by the use in the herd of only those cattle that had been repeatedly found negative to agglutination tests—not a single instance of positive agglutination was discovered. On the other hand, out of 350 patients who had been at A previous to this change, positive agglutination tests were reported in 10

instances. Seven of these had also been found to possess agglutinins in the previous study, 2 had not been tested at the previous series, although they had been at A for a long time, and the 10th had had a negative agglutination test taken soon after his admission, several months before the herd had been cleaned up, and therefore had been drinking the milk from positive cattle for several months after this test had been made.

On the tests made in this re-check, 25 patients, who had shown positive tests on one or more occasions previously, were found to be negative at this time. More than half of these had already lost their agglutinins when tested in August, within 4 months of the time the herd was cleaned out, and most of the others tested in August had shown a marked drop from a much higher titer. The rate at which agglutinins were lost was not, of course, exactly the same in each case, but the great majority of the curves followed approximately the same slope, representing generally a loss of about half the agglutinin titer every 60 days. Successive readings on the sera that did not entirely lose their agglutinins also showed approximately the same rate of disappearance of the titer (Graph A).

The significance of this uniform reduction in the titer of the sera is not entirely clear. If it were merely a passive immunity due to absorptions of antibodies in the milk, the rate of disappearance of the antibodies should be many times faster, since we have learned from studies of passive immunization against diphtheria, scarlet fever, and other diseases that the antibodies in injected sera are usually completely excreted within a few weeks. On the other hand, active immunization from true infection would be expected to persist much longer, and to manifest less uniformity in its disappearance. The most plausible conclusion appears to be that the organisms do enter the tissues, and

GRAPH 'A'
CHANGES IN AGGLUTININ TITER

thus give rise to active immunity, but that they are unable to produce real infection, and rapidly die off, or perhaps that the antigenic protein products of the bacteria may be absorbed without viable organisms even penetrating the intestinal mucosa. If such antigenic absorption were possible, it might explain why the immunity is so mild and why it disappears so consistently, as the antibodies following vaccination in typhoid and similar conditions. In so

far as this may be the true situation, of course, it serves greatly to minimize the public health importance of milk-borne bovine infectious absorption. It is premature to assert the impossibility of such antigen absorption through the intestinal tract, but it may at least be recognized that it is very unlikely, and that actual invasion by organisms of very low virulence and therefore short lived infections are a much more probable solution.

CONCLUSIONS

The results of this investigation indicate that the ingestion of raw milk obtained from cows infected with contagious abortion and showing positive tests for agglutinins to *Br. abortus* in their blood is responsible for the development of similar agglutinins in the blood of some consumers. This has been found to occur in about 8 per cent of those continuously exposed to the ingestion of heavily infected raw milk, but varies with the duration of exposure, the amount of infection in the herd, and the amount of the raw milk so consumed. No particular sex or age susceptibility to this infection has been found. No effect of tuberculosis or other disease upon the development of such agglutinins is apparent, except in so far as they affect the amount of exposure to the infected milk. The development of such agglutinins has not been found to exercise any marked effect on the course of the tuberculosis. More than half of the patients developing agglutinins to *Br. abortus* give no other manifestation of the infection and, therefore, come well within the groups described as sub-clinical, asymptomatic, or purely serological brucellosis. About one-eleventh of them manifest clinical symptoms warranting a diagnosis of undulant fever, and an additional group present other symptoms that might be attributable to the same cause. The disease manifestations are, however, comparatively mild, conforming, therefore, to the bovine type of infection, as described by Theobald Smith, rather than to the more virulent types that are frequently described from caprine or porcine sources. It constitutes, however, a definite disease entity, and cannot be disregarded.

Effectiveness of Radio in Health Education

C. E. TURNER, DR.P.H., F.A.P.H.A. (*Life Member*)
VIVIAN V. DRENCKHAHN, AND MARIA W. BATES

Department of Biology and Public Health, Massachusetts Institute of Technology, Cambridge, Mass.

THIS brief study was made in an attempt to determine the size of the radio audience which listens to educational health broadcasts, and to determine what effect these broadcasts produce on the health behavior of listeners. We also wished to find out who listens, when he listens, and what kind of broadcast is preferred.

Reports of only two previous investigations of radio health broadcasts had apparently been published. The first¹ reported that in one American city, (Racine, Wis.) where 6.9 per cent of the homes were reached by public health nurses, 33 per cent of the homes in May and 29 per cent in November listened more or less regularly to broadcasts of the local health department. The other investigator² attempted to check the radio audience of a county board of health broadcast (Jefferson County, Ala.) by the number of persons requesting copies of the lectures. Fifty people sent for these reprints. In the belief that only 1 per cent of a radio audience request material announced during a broadcast, it was estimated that 5,000 people were reached during the 12 lectures.

The effectiveness of radio in health education is important because of the time and money spent by official and nonofficial health agencies throughout the United States in preparing and in giving health broadcasts. In 1931, the

U. S. Public Health Service reported that 15 of the 48 state health departments broadcast regularly (weekly, monthly, or semi-monthly), and 6 others broadcast irregularly on public health subjects. Questionnaires filled in by the health departments of the 200 largest cities in the country showed that 18 of these cities broadcast regularly and 17 at irregular intervals on health subjects.³

Through the courtesy of Elizabeth C. Nickerson, Director of the Bureau of Public Health Instruction, Connecticut State Department of Health, the writers learned of a study made by that department in 1931 concerning the amount of broadcasting done by medical societies throughout the United States. Ten of the 15 county medical societies who reported in this study broadcast regularly. The state medical societies of Illinois, Massachusetts, Michigan, and New Jersey, as well as the San Francisco Heart Commission and the New York Tuberculosis and Health Association were reported to be broadcasting once a week or oftener.

In 1933, of 312 national voluntary organizations with public service objectives who returned questionnaires to the National Advisory Council on Radio and the Federal Office of Education, 45 reported broadcasting regularly and 76 occasionally.⁴ Another study made the same year showed that 10 state depart-

ments of education were sponsoring regular radio programs. Of 126 educational broadcasts given by 7 state departments of education, and classified according to subjects, 5 were on physical education and health topics.⁵

THE GROUP STUDIED

The data of this study were collected by means of questionnaires filled in by secondary school pupils in two Massachusetts communities, Arlington and Malden. Arlington (population 36,000) has a good program of general education in its public schools, but had not had a directed health education program until the year this study was made. Malden (population 58,000) has had a well organized health education program for 12 years.

Through a process of trial and revision a questionnaire was developed to be used as a social study project in social science classes in the secondary schools. Careful directions were given to the classroom teachers. Each pupil was asked to fill out one questionnaire for himself in the classroom, and to take home a second identical form to fill out for some member of his household over 21 years of age. Pupils were asked not to sign the questionnaire. They understood that their records were not to be graded either for them as individuals or for a class record, and that they were contributing to the study of a large group. This approach was made in order to get a careful and honest report from the pupils.

The items of the questionnaire were as follows:

1. City
2. School
3. Grade
4. Teacher
5. Sex
6. Age (If this sheet is being filled in at home for a member of your household, please answer questions 7 and 8.)
7. Relation to pupil
8. Occupation
9. Have you a radio in your home?

10. Is your radio working?

11. Give the following information about the health broadcasts you have heard in the week ending Sunday at midnight:

(a) What was the broadcast about?

(b) Name the health department, association or company which gave the broadcast

(c) Did you listen through to the end of the broadcast?

12. If you listen regularly to health broadcasts, list them below:

(a) Name the agency

(b) Tell why you like or do not like the broadcast

(c) How do you get information about this broadcast?

13. State whether you prefer a health broadcast to be (1) talk, (2) dialogue, (3) play, (4) questions and answers.

14. List the suggestions given in health broadcasts which you have put into practice, and name the agency which gave each suggestion:

(a) What was the suggestion?

(b) Name the agency

15. State the time of day you usually listen to the radio morning, afternoon, evening. (Do not check, give hours as from 7 to 8 o'clock.)

16. Upon what subjects would you like to hear health broadcasts?

17. What health literature have you sent for as a result of radio broadcasts given during the week ending last Sunday at midnight?

18. What health products do you hear advertised over the radio?

19. What is the best straight health broadcast (not an advertising program) that you remember?

20. Date (Additional information, which should be numbered according to the questions, may be written on the other side of this sheet.)

The total number of questionnaires tabulated was 2,143. Of these 1,348 (62.8 per cent of the total number) were filled in by pupils in the classrooms, while the remaining 795 (37.2 per cent) were filled in by pupils of the same group for members of their households. Of the 795 adults included in the study, 486 (61.2 per cent) were women, and 309 (38.8 per cent) were men. Boys numbered 713 (52.9 per cent) of the total number of pupils, and girls 635 (47.1 per cent). More than

60 per cent of the total number of pupils were between the ages of 16 and 18 years, and 97 per cent between 13 and 19.

The occupations of men and women included in this study are as follows:

Men	Per Cent	
114	36.9	Engaged in business
76	24.6	Skilled laborers
47	15.2	Unskilled laborers
20	6.5	Professional men
52	16.8	All others
<i>Women</i>		
381	78.5	Housekeepers
75	15.4	Engaged in business
30	6.1	All others

RADIOS

Nearly every home (95 per cent) had a radio. Nearly all of these (92 per cent) were in working order.

TYPES OF PROGRAMS MOST FREQUENTLY HEARD

Many advertising programs were listed as health programs. The products

most frequently heard advertised over the radio for their health value were, in order of frequency, food, toothpaste, and medicine. Such advertising programs were reported as health broadcasts 1,280 times per 1,000 questionnaires returned from Arlington and 486 times per 1,000 questionnaires returned from Malden.

The programs dealing directly with some phase of health (non-entertainment programs) most often heard during the week preceding the questionnaire were, in order of frequency: (1) The Tower Health Exercises of the Metropolitan Life Insurance Company (183 times), (2) Health Talks for Horlick's Malted Milk (133 times), (3) Talks on health of the Parker Dental System (84 times), (4) Health talks for Stanco, Inc. (53 times), (5) Talks on health and disease for Sharpe and Dohme (32 times), (6) Talks on child training and mental hygiene for Cream of Wheat Corporation (16 times), (7) Massa-

FIGURE I

chusetts Department of Public Health (7 times).

There had been 4 State Health Department broadcasts during the period reported upon. This represents roughly 1 person out of 1,000 who heard each of these broadcasts. The number 7 is so small, however, that it is a poor index of the number of people listening to this type of program. One-tenth of one per cent may be too high or too low.

It would seem that health departments might do well to consider ways and means of securing larger audiences. It might be worth while to coöperate with such already-formed groups as women's clubs, societies, or school health classes, by supplying information at pre-arranged times on health topics which are being considered in their programs. For example, members of a women voters' organization would be interested in listening to a broadcast on current public health bills before their state legislature, if this were the subject of their next meeting. Members of mothers' clubs are always interested in securing recent information from authoritative sources on different phases of child care. Many schools are equipped with radios which could be used at pre-arranged times to pick up broadcasts whose special purpose was the presentation of a health message for children.

The 7 instructional health programs mentioned above were reported as being heard 274 times per 1,000 questionnaires from Malden but only 200 times per 1,000 for Arlington. In Arlington, 8.2 per cent, and in Malden, 13.5 per cent of the people reported that they listen regularly to such programs.

TYPES OF BROADCASTS PREFERRED

Plays as a type of health broadcast were preferred by 954 persons or 60.2 per cent of those expressing a preference. A larger proportion of boys and girls preferred this type of broadcast than did men and women. More persons in Arlington than in Malden showed a preference for plays.

"Questions and answers" were preferred by 295 persons, or 18.6 per cent of all groups reporting. A smaller proportion of girls preferred this type of health program than did men, women or boys. A larger percentage of persons in the Malden group preferred "questions and answers" than did those in the Arlington group.

Two hundred and twelve persons (13.4 per cent of those answering) reported a "talk" as their choice in radio health programs. This choice was given by 28.5 per cent of the men; 20.1 per cent of the women; 12.7 per cent of the boys; and 4.9 per cent of the girls.

TABLE I

PERCENTAGE OF THE DIFFERENT GROUPS REQUESTING PROGRAMS ON DIFFERENT SUBJECTS

<i>Subject</i>	<i>All Groups (2,143) Per Cent</i>	<i>Men (309) Per Cent</i>	<i>Women (486) Per Cent</i>	<i>Boys (713) Per Cent</i>	<i>Girls (635) Per Cent</i>
The Body	5.8	5.8	5.1	7.7	4.2
Teeth	5.2	4.5	5.8	4.2	6.5
General Health	4.3	6.1	4.8	3.9	3.5
Diseases	4.0	3.4	3.7	4.2	4.1
Food	3.2	2.3	3.3	2.2	4.9
Diet	2.6	2.6	5.8	1.2	1.9
Complexion	2.3	0.3	2.3	0.9	4.7
Exercise	1.6	1.3	0.6	2.7	1.4
Hair	1.0	0.9	0.4	0.7	1.9
Child Care	0.8	0.9	2.9
All Others	6.3	5.5	7.0	7.5	5.0

More persons in Malden than in Arlington preferred talks (17.4 per cent as compared with 10.5 per cent).

Fewer persons (only 9.9 per cent of those reporting) expressed a choice for dialogues.

THE BEST TIMES OF DAY FOR BROADCASTING

Figure I shows the per cent of adults and the per cent of secondary school pupils who usually listen to the radio at different times of day. This is, of course, an index of the number of people listening to all programs (primarily entertainment programs) at any one time.

HEALTH SUGGESTION FOLLOWED

No one reported following advice given in non-advertising programs, although 109 persons, about 5 per cent of all persons included in the study, reported putting into practice suggestions given by various advertising health broadcasts. These suggestions put into practice included such items as eating cereals, brushing the teeth, going to a dentist, and eating yeast.

SUBJECTS WHICH WERE DESIRED

Thirty different subjects were named upon which men, women, boys, and girls would like broadcasts. Table I shows the 10 subjects which were reported most frequently, together with the per cent of the total group, and the per cent of the total number of men, women, boys, and girls who were interested in hearing broadcasts on these subjects.

Seven hundred and twelve persons (33 per cent of the total number answering the questionnaire) reported that they would like to hear radio health broadcasts. Of these, 339 were from Arlington and 373 from Malden. These totals represent 41 per cent of the total group from Malden and 28 per cent of the total group from Arlington.

METHODS OF SECURING ADVANCE INFORMATION

Advance information for radio health programs was obtained in the great majority (85 per cent) of the cases reporting, from the newspaper. Other sources of information were the radio (4 per cent of those reporting) and friends (7 per cent of those reporting). Still others (the remaining 4 per cent) tuned in by chance.

BEST STRAIGHT HEALTH BROADCASTS

An appreciable number of people (317) listed the best health broadcast each had ever heard. Those broadcasts reported the most number of times were in the order mentioned, (1) Tower Health Exercises of the Metropolitan Life Insurance Company (105 times), (2) Health Talks for Horlick's Malted Milk (68 times), (3) Health Talks for Stanco, Inc. (59 times), (4) Talks on health for the Parker Dental System (19 times), (5) Massachusetts Department of Public Health (17 times), (6) Talks on Child Training and Mental Health for the Cream of Wheat Corporation (13 times), (7) Talks on Health and Disease for Sharpe and Dohme (11 times), (8) Talks on Health sponsored by the National Broadcasting Company (8 times), and (9) all others (17 times).

SUMMARY

Data collected by means of questionnaires filled in by 2,143 secondary school pupils and adults in two Massachusetts communities, nearly all of whom owned radios, showed that food, toothpaste, and medicine, in the order named, were the products most frequently heard advertised over the radio for their health value.

Instructional health broadcasts were reported 256 times per 1,000 questionnaires returned from Malden, and 217 times per 1,000 questionnaires returned from Arlington.

Plays, questions and answers, talks, and dialogues, in the order named, were reported as being the types of health broadcasts preferred.

The best time of day for broadcasting is between 6:30 and 11:00 in the evening, reaching a peak between 8:00 and 8:15.

No one reported following suggestions given in non-advertising programs, but about 5 per cent of the total group said they put into practice suggestions given in advertising health broadcasts.

About one-third of the people would like to hear broadcasts on health subjects.

More people were interested in radio health programs and greater discrimination was shown as to what constitutes a health broadcast in the city with the well organized health education program in the schools.

It would appear that not more than 1 person out of 1,000 listened to State Health Department broadcasts.

CONCLUSIONS

1. Health education in schools increases the

interest of the population in popular health instruction and increases their discrimination as to the quality of health programs.

2. It might be worth while for health departments to arrange broadcasts for particular audiences (women's clubs, civic groups, secondary schools) on topics which these groups are considering.

3. A half-minute message introduced between other programs might also serve to announce health department publications, or to offer a terse bit of timely health advice.

4. It seems apparent that dramatization is the most acceptable form of health broadcast.

5. The general lack of discrimination as to the reliability or unreliability of broadcast health advice shows the need for controlling health broadcasting and for instruction concerning pernicious advertising.

6. Our experience with the present study suggests that better results could be obtained by securing exact information concerning a particular typical day.

Babies Huskier Now

BABIES born in New York State today have a far better chance of surviving the first year of life than did those born 25 years ago, according to the 1933 annual report of the Division of Vital Statistics. Infant mortality in the state has been declining not only in terms of the number of births but also

in relation to all deaths. Twenty-five years ago, out of 100 deaths of all ages, 19 were of infants under 1 year of age; in 1933 the proportion dropped to 7. In other words, the rate of infant deaths has declined considerably faster than the general death rate.—*New York State J. Med.* 35, 3:116 (Feb.), 1935.

Use of Convalescent Measles Serum to Control Measles in a Preparatory School

J. ROSWELL GALLAGHER, M.D.

School Physician, The Hill School, Pottstown, Pa.

THE suppression of a threatened outbreak of measles in a preparatory school is of importance because of the loss of school days and the inconvenience which may result; neither the incidence of complications nor the attendant seriousness of this disease is as important a factor among the members of this age group as in younger children, but the disease spreads with extreme ease and attempts to control it by the isolation of contacts are relatively futile. The inconvenience which an outbreak of measles may cause and the extent to which it may spread, even when a group is under careful medical supervision, are illustrated in Table I; such experiences have been duplicated frequently among other groups of preparatory school boys.

Since 1918 when Nicolle and Conseil⁴ advocated the use of convalescent measles serum as a prophylactic agent it has been frequently used in attempts to control measles, particularly in institutions housing young children. Zingher and Park,⁸ Park and Freeman,⁵ and many others have reported very satisfactory results from its use; however, because convalescent serum is somewhat difficult to obtain, another effective agent has been sought by various investigators. Tunncliffe and Hoyne⁷ and Peterman⁶ have reported success with a serum produced in goats which had been inoculated with a diplo-

coccus isolated from patients suffering from measles; other workers¹ have noted no preventive action with that serum. It is now generally agreed that measles is caused by a filtrable virus and that the coccus described by Tunncliffe is a secondary invader. The ease with which parental whole blood may be obtained and the satisfactory results reported by many workers since the introduction of this method by Degkwitz³ have made it the most common method of prophylaxis in use at the present time; usually 15 c.c. of whole citrated blood obtained from a parent is injected into each buttock of the child.¹

In attempting to suppress an outbreak in a preparatory school, however, the use of convalescent serum remains the most practical procedure. Park⁵ believes that the immunity conferred by this serum will persist for from 2 to 4 weeks, and that in those individuals who develop attenuated cases a permanent immunity will nevertheless be produced. Zingher⁸ has pointed out that the infectivity during the prodromal stage is distinctly less in an individual who subsequently develops an attenuated case rather than an unmodified one. The majority of previous reports have dealt with results obtained in children of 3 years of age or less, and the dose which should be given the average

adolescent can only be judged approximately. Park⁵ has advocated the use of 6 c.c. of serum for children less than 3 years of age, and 10 c.c. for those 3 years of age or older. Debre² suggests a minimum dose of 3 c.c. for infants and would add 0.5 c.c. for each additional 6 months of age, up to a maximum dose of 15 c.c. at 15 years. The serum should be administered before the 5th day of the incubation period; the earlier the serum is given the better is the possibility that the disease will be prevented rather than attenuated. Serum should be obtained from a convalescent individual between the 10th and 40th day following the return of his temperature to normal; a preservative should be added if the serum is not used within a few days.⁵

The present paper reports our experience with the use of convalescent serum in an attempt to control a threatened outbreak of measles in a boys' preparatory school during the winter of 1934.

Table I shows the incidence of measles together with the number of Infirmary days involved during outbreaks at a preparatory school in 1926 and 1929. No convalescent serum was used.

METHOD AND RESULTS

On January 1, 1934, C.Y. was exposed to an individual who developed measles on the following day. Upon his return to school he was quarantined, and on January 12 his prodromal symptoms began; the rash appeared on January 16. F.L. and R.D. were pa-

tients in the same infirmary from January 4 to 14 and January 15 to 16 respectively. On January 27, F.L. was re-admitted to the infirmary, and on January 28 his rash appeared; R.D. was re-admitted on January 28, and his rash appeared on January 30. In Table II data concerning these 3 cases are presented.

Table II gives data concerning the cases which might have initiated an outbreak of measles. At the development of cases F.L. and R.D., and because of the failure to quarantine them during

* Each of these individuals developed an attenuated case; in each instance serum NYC had been given.

the entire prodromal period, it seemed likely that many other cases would develop subsequently. Investigation showed that 66 of the 330 boys in the school had not had measles; their ages ranged from 12 to 20 years. These boys were divided into three groups, graded as to the likelihood of their having been exposed; group I included boys known to have been in contact with F.L. or R.D.; group II consisted of the boys who probably had been exposed; and group III included older boys whose chance of contact was somewhat more remote. The likelihood of contact was based upon seating arrangements in chapel, dining hall, and classrooms, dormitory arrangement, athletic contacts, etc. Such a division became necessary because of the limited amount of serum available, and provided a means of adjusting the dose in relation to possibility of infection.

On January 30 convalescent serum obtained either from C.Y. on the 10th day after his temperature had become normal, or from the Bureau of Laboratories of the City of New York, was given to 62 of the 66 boys in the school who had not had measles; 1 of the remaining boys received the serum on February 2 and 2 others on February 3; 1 boy did not receive serum. The names of the boys in each group were arranged alphabetically and these two sera were assigned alternately; because the supply of serum NYC was greater a somewhat larger number received that serum. Since the prodromal symptoms appeared in F.L. on January 24 and

since R.D. was hospitalized on January 28, it is obvious that serum was given to 62 boys at an interval of from 2 to 6 days following possible exposure. The serum was injected into the upper outer quadrant of the buttock. In Table III will be seen the number of boys who received each dose of either serum, together with the total number of boys who subsequently developed measles.

COMMENT

In an institution in which there were 66 adolescents who were probably susceptible to measles, convalescent measles serum was used as a prophylactic agent following the appearance of 3 cases of measles in the student body. In such a group, if one is to judge by past experience, at least 25 per cent would probably develop measles before the subsidence of the outbreak. Following the prophylactic therapy, however, only 3 cases of measles developed in this group and each of these cases was in striking contrast in severity to the original cases; in Tables IV and V we have tabulated certain clinical data which will indicate the differences between the unmodified and the attenuated cases.

Despite the fact that no untreated control group was employed in this study, we feel, on the basis of past experience, that the subsidence of this outbreak was due to the use of the convalescent serum; it is unlikely that anyone who has dealt with measles in a similar situation will believe otherwise. The question of proper dosage in

* Exclusive of prodromal period

this age group is difficult to determine accurately. The development of attenuated cases in J.P. and C.S. despite the fact that prophylaxis must have been given them at most within 72 hours following exposure, suggests that they were particularly susceptible. It may be that a larger dose would have prevented these cases, but if one were to judge by this single experience, a dose of 10 c.c. will produce satisfactory results in the vast majority of instances. It is interesting that each of the 3 individuals developing attenuated measles had had serum NYC; it is not unlikely that this serum had a lower antibody content than serum CY which was only 24 hours old.

SUMMARY

1. In a threatened outbreak of measles in a group of preparatory school boys, 66 of whom had not had measles, convalescent measles serum was used prophylactically. Only 3 cases of measles, all decidedly attenuated, subsequently developed in this group. On

the basis of past experience, at least 25 per cent of this group might have been expected to develop measles.

2. The use of convalescent measles serum is suggested as the most practical method of controlling an outbreak of measles among adolescents in a preparatory school or in a similar situation. A dose of 10 c.c. is considered adequate for members of this age group.
